Early recognition of airway obstruction is crucial for you to be able to provide emergency medical care effectively. Obstruction by a foreign body can result in a **mild airway obstruction** or a **severe airway obstruction**.

Patients with a mild airway obstruction (partially obstructed airway) are still able to exchange air but will have varied degrees of respiratory distress. Great care must be taken to prevent a mild airway obstruction from becoming a severe airway obstruction.

With a mild airway obstruction, the patient can cough forcefully, although you may hear **wheezing** between the coughs. As long as the patient can breathe, cough forcefully, or talk, you should not interfere with the patient's efforts to expel the foreign object on their own. Continue to monitor the patient closely and encourage the patient to continue coughing. Abdominal thrusts are usually not effective for dislodging a mild airway obstruction. Attempts to remove the object manually could force the object farther down into the airway and cause a severe obstruction. Continually reassess the patient's condition and be prepared to provide immediate treatment if the mild obstruction becomes a severe obstruction.

With poor air exchange, the patient has a weak, ineffective (not forceful) cough and may have increased difficulty breathing, **stridor** (a high-pitched noise heard primarily on inspiration), and cyanosis. Stridor is an indication of a mild upper airway obstruction. You must quickly recognize this situation and provide immediate care.

For patients with mild airway obstruction with poor air exchange, treat immediately as if there is a severe airway obstruction.

Patients with a severe airway obstruction (completely obstructed airway) cannot breathe, talk, or cough. One sure sign of a severe obstruction is the sudden inability to speak or cough immediately after eating. The person may clutch or grasp the throat (universal distress signal), begin to turn cyanotic, and make frantic attempts to breathe. There is little or no air movement. Ask the responsive patient, "Are you choking?" If the patient nods "yes," provide immediate treatment. If the obstruction is not cleared quickly, the amount of oxygen in the patient's blood will decrease dramatically. If not treated, the patient will become unresponsive and die.

Some patients with a severe airway obstruction will be unresponsive. You may not know that an airway obstruction is the cause of their condition. There are many other causes of unresponsiveness and respiratory distress, including stroke, heart attack, trauma, seizures, and drug overdose. A complete and thorough patient assessment by you,

FIGURE 11-54 When you open the airway and attempt ventilations, it will be obvious to you if the airway is still blocked.

© Jones & Bartlett Learning.

therefore, is key in providing appropriate emergency medical care.

If a patient is found unresponsive and does not appear to be breathing, you should begin CPR with high-quality chest compressions. After 30 compressions, when you open the airway and attempt two ventilations, it will become clear that the airway is blocked (**FIGURE 11-54**). Often the compressions may have been enough to clear the airway; however, if this has not cleared the obstruction and you are unable to ventilate the patient after two attempts (the chest does not visibly rise), or you feel resistance when ventilating, consider the possibility of an airway obstruction. Resistance to ventilation can also be a result of poor lung compliance. Chapter 15, *BLS Resuscitation*, discusses steps for emergency medical care of a foreign body airway obstruction in detail.

Recall that aspiration of blood or other fluid is dangerous for the patient. In addition to potentially obstructing the airway, aspiration destroys delicate bronchiolar tissue, introduces pathogens into the lungs, and decreases the patient's ability to ventilate (or be ventilated). Suction should be readily available for any patient who is unable to maintain their own airway. Always assume that patients who require emergency medical care have a full stomach.

Supraglottic Airway Devices

King LT Airway

The **King LT airway** is a latex-free, single-use, single-lumen airway that is blindly inserted into the esophagus (**FIGURE 11-55**). You can use the King LT

FIGURE 11-55 The King LT is a single-lumen airway that is blindly inserted into the esophagus. The King LT-D model is shown here.

Courtesy of King Systems.

FIGURE 11-56 Placement of the King LT airway. When properly placed, the distal cuff seals the esophagus, and the proximal cuff seals the oropharynx.

© Jones & Bartlett Learning.

to provide positive-pressure ventilation to apneic patients and maintain a patent airway in unresponsive patients who are breathing spontaneously, but who require advanced airway management. The King LT is available in both adult and pediatric sizes.

The device consists of a curved tube with ventilation ports located between two inflatable cuffs. Both cuffs are inflated simultaneously using a single valve/pilot balloon. When the airway is properly placed in the esophagus, the distal cuff seals the esophagus, and the proximal cuff seals the oropharynx (**FIGURE 11-56**). Openings located between these two cuffs provide ventilation of the lungs after positioning is confirmed. You can use the King LT as a rescue airway device.

TABLE 11-12 Sizes and Patient Criteria for the King LTS-D

Size	Connector Color	Patient Criteria: Height and Weight ^a	Cuff Volume
0	Transparent	11 lb (5 kg)	10 mL
1	White	11–26 lb (5–12 kg)	20 mL
2	Green	35–45 inches (90–115 cm) or 26–55 lb (12–25 kg)	35 mL
2.5	Orange	41–51 inches (105–130 cm) or 55–77 lb (25–35 kg)	40–45 mL
3	Yellow	4–5 ft (122–155 cm)	50–60 mL
4	Red	5–6 ft (155–180 cm)	70–80 mL
5	Purple	>6 ft (180 cm)	80–90 mL

^aSizes 0 and 1 are weight based. Sizes 2 and 2.5 are weight and/or height based. Adult sizes (sizes 3–5) are height based.

Data from: Ambu King LTS-D Disposable Laryngeal Tube. Ambu USA website. December 2015 version. http://www.ambuusa.com/usa/products/anesthesia/product/king_lts-d%E2%84%A2_disposable_laryngeal_tube-prod17813.aspx. Accessed February 21, 2017.

Two types of King LT airway are available: the King LT-D and the King LTS-D. The King LTS-D is the more commonly used device; it is available in seven sizes that are based on the patient's height and/or weight. Each size has a different color of proximal connector and requires different cuff inflation pressures. **TABLE 11-12** lists sizes and patient criteria for the King LTS-D. Each kit contains a single King LT, a syringe for cuff inflation, water-soluble gel, and instructions for use.

The King LT-D (see Figure 11-56) and the King LTS-D share most of the same features. Both have a proximal pharyngeal cuff and a distal cuff and several ventilation outlets at the distal part of the tube. The distal end of the King LT-D is closed, whereas the distal end of the King LTS-D is open. This opening permits insertion of a suction catheter (up to size 18F) through a gastric access lumen on the proximal end of the King LTS-D for gastric decompression (**FIGURE 11-57**).

Indications and Contraindications for the King LT Airway

The King LT airway should be considered an alternative to bag-mask ventilation when a rescue device is required for a failed intubation attempt. The King LT airway is intended for airway management in patients who are taller than 4 feet. It has the same disadvantages, complications, and special considerations as the Combitube (discussed later in this chapter).

**FIGURE 11-57** The King LTS-D.

Courtesy of Candice M. Thompson, NREMT-P.

Regarding contraindications, the King LT airway does not protect the airway from the effects of vomiting and aspiration. High airway pressures may cause air to leak into the stomach or out of the mouth. The King LT airway should not be used in patients with an intact gag reflex, patients with known esophageal disease, or patients who have ingested caustic substances. As with other advanced airway devices, confirm proper placement by observing

chest rise, auscultating the epigastrium and lungs, and using a secondary confirmation device.

Complications of the King LT Airway

It is reasonable to assume that laryngospasm, vomiting, and possible hypoventilation may occur. Trauma may also result from improper insertion technique. Ventilation may be difficult if the pharyngeal balloon pushes the epiglottis over the glottic opening. If this occurs, withdraw the device while gently bagging the patient to assess ventilation—without deflating the cuffs—until ventilation becomes easier.

Insertion Technique

As previously discussed, the King LT airway comes in five sizes; the patient's height and weight will determine the size that you should use. The steps for inserting the King LT airway are shown in **SKILL DRILL 11-12**.

The Laryngeal Mask Airway

The **laryngeal mask airway (LMA)** (**FIGURE 11-58**) was originally developed for use in the operating room. It provides a viable option for cases that require more airway support than mask ventilation but do not require intubation.

The LMA is designed to provide a conduit from the glottic opening to the ventilation device. This is achieved by surrounding the opening of the larynx with an inflatable silicone cuff positioned in the hypopharynx. When properly inserted, the opening of the LMA is positioned right at the glottic opening. The tip is inserted into the proximal esophagus, the lateral portions in the piriform fossae, and the upper border at the base of the tongue. The inflatable cuff conforms to the contours of the airway and makes a relatively airtight seal (**FIGURE 11-59**).

The LMA has many advantages compared with ventilating the unprotected airway with a mask. The LMA has been shown to provide better oxygenation than mask ventilation with an oral airway, and ventilation with an LMA does not require the continual maintenance of a mask seal. Compared with an ET tube, LMA insertion is easier. There is substantially less risk of soft-tissue, vocal cord, tracheal wall, and dental trauma than with ET intubation and other forms of intubation that rely on blocking the esophagus. The LMA provides protection from upper airway secretions, and the tip of the LMA wedged into the proximal esophagus most likely provides some obturation.

The main disadvantage of the LMA, especially in emergencies, is that it does not provide as much protection against aspiration as does ET intubation.

Skill Drill 11-12 Inserting a King LT Airway

Step 1

Take standard precautions.

Step 2

Preoxygenate the patient with a bag-mask device and 100% oxygen.

Skill Drill 11-12 Inserting a King LT Airway (continued)

Step 3

Gather your equipment. Choose the proper size of King LT airway for the patient. Test the cuff for proper inflation. Ensure all air is removed from the cuff before insertion. Lubricate the tip of the device with a water-soluble gel for easy insertion and minimal airway damage.

Step 4

Place the patient's head in a neutral position, unless contraindicated (use the jaw-thrust maneuver if you suspect trauma). In your dominant hand, hold the King LT at the connector. With your other hand, hold the patient's mouth open while positioning the head. Insert the tip of the King LT airway into the midline of the mouth.

Step 5

Advance the tip beyond the base of the tongue. If you meet resistance, then rotate the device slightly, change your angle, and advance it again. Continue to gently advance the device until the base of the connector is aligned with the patient's teeth or gums. Do not use excessive force. Inflate the cuff with the recommended amount of air or just enough to seal the device.

Step 6

Attach the tube to the ventilation device and confirm tube placement by auscultating the lungs and epigastrium and attaching waveform capnography. Add additional air to the cuff to maximize airway seal, if needed; however, avoid exceeding the manufacturer's recommended maximum amount of air. After placement is confirmed, continue to ventilate the patient.

FIGURE 11-58 The laryngeal mask airway.

FIGURE 11-59 When properly positioned, the opening of the laryngeal mask airway is at the glottic opening, the tip is at the entrance of the esophagus, the lateral portion is in the piriform fossae, and the upper border is at the base of the tongue.

© Jones & Bartlett Learning.

The LMA may actually increase the risk of aspiration if the patient regurgitates because the patient's stomach contents would most likely be directed into the trachea.

During prolonged LMA ventilation, some air may be insufflated into the stomach because the seal made in the airway is not airtight. Because of the risk of aspiration, it is unlikely that the LMA will ever replace ET intubation in prehospital emergency care. The LMA should not be considered a primary airway for emergency patients, but it may have a role. For a patient who cannot be intubated, the LMA should be considered superior to mask ventilation.

Indications and Contraindications for the LMA

The LMA should be considered as one possible alternative to mask ventilation only when the patient cannot be intubated. Do not consider the LMA as a primary airway in emergency situations.

The LMA is less effective in obese patients and should not be used in patients with morbid obesity. Patients who are pregnant or have a hiatal hernia are at an increased risk for regurgitation and must be evaluated carefully if LMA use is considered. The LMA is ineffective for the ventilation of patients requiring high pulmonary pressures (such as patients with COPD or heart failure).

Complications of Using the LMA

The most substantial complications associated with use of the LMA involve regurgitation and subsequent aspiration. The product literature states that the LMA should be used only in patients who are fasting. Unfortunately, this would eliminate all patients in emergency situations. You must weigh the risk of aspiration against the risk of hypoventilation with bag-mask ventilation in the context of a given clinical scenario.

Observe the patient for clinical indications of adequate ventilation (chest rise, breath sounds) during LMA ventilation. Hypoventilation of patients who require high ventilatory pressures can also occur, and the patient should be monitored for evidence of upper airway swelling.

Equipment for the LMA

The LMA comes in seven sizes and is sized based on the patient's weight. The device consists of a tube and the mask or inflatable cuff. The cuff provides a collar that is designed to position the opening of the tube at the glottic opening when inflated. Two vertical bars are present at the opening of the tube to prevent occlusion. The proximal end of the tube is fitted with a standard 15/22-mm adapter that is compatible with any ventilation device. The cuff has a one-way valve assembly and should be inflated with a predetermined volume of air (based on the size of the airway) (**FIGURE 11-60**).

Insertion Technique

Before insertion, check and prepare all equipment. The steps for using an LMA are summarized in **SKILL DRILL 11-13**.

FIGURE 11-60 The laryngeal mask airway with the cuff inflated.

© Jones & Bartlett Learning.

Continuously and carefully monitor for regurgitation in the tube. The LMA can be easily dislodged because it was not designed for patients who are being transported. Carefully attend to the airway during any patient movement and be prepared to bag-mask ventilate if the LMA becomes dislodged.

Documentation & Communication

If adverse events, such as bleeding or trauma, occur with the use of advanced airway devices, then be sure to document these occurrences on the patient care report.

Skill Drill 11-13 LMA Insertion

Step 1

Take standard precautions. Check the cuff of the LMA by inflating it with 50% more air than is required for the size of airway to be used.

Step 2

Deflate the cuff completely so that no folds appear near the tip. Deflation is best accomplished by pressing the device, cuff down, on a flat surface to remove all wrinkles from the cuff.

Step 3

Lubricate the outer rim of the device.

Step 4

Preoxygenate the patient before insertion. Do not interrupt ventilation for more than 30 seconds to accomplish airway placement. Place the patient in the sniffing position.

(continues)

Skill Drill 11-13 LMA Insertion (*continued*)**Step 5**

Insert your finger between the cuff and the tube. Place the index finger of your dominant hand in the notch between the tube and the cuff. Open the patient's mouth. Lift the jaw with one hand and begin to insert the device with the other hand.

**Step 6**

Insert the LMA along the roof of the mouth. The key to proper insertion is to slide the convex surface of the airway along the roof of the mouth. Use your finger to push the airway against the hard palate. After it slides past the tongue, the LMA will move easily into position.

**Step 7**

Inflate the cuff with the amount of air indicated for the airway being used. If the LMA is properly positioned, then it will move out of the airway slightly (0.5 to 0.75 inch [1 to 2 cm]) as it moves into position (a good indication that the LMA is in the correct position).

**Step 8**

Begin to ventilate the patient. Confirm chest rise and the presence of breath sounds. Continuously and carefully monitor the patient. Monitor ETCO_2 if available.

i-gel

The **i-gel** supraglottic airway is inserted in a manner similar to the LMA. This airway device was designed to create a noninflatable, anatomic seal of the pharyngeal, laryngeal, and perilaryngeal structures, while avoiding compression trauma that may occur from devices with an inflatable cuff (**FIGURE 11-61**). The i-gel is a common rescue airway device and is a reasonable alternative when intubation is unsuccessful.

The i-gel features an integral bite block, a gastric access channel that allows for passage of a 12F gastric tube, a supplemental oxygen inlet port to facilitate passive oxygenation, and a support strap to secure the i-gel in position. A color-coded, proximal hook ring indicates the size of the i-gel and serves as an anchor for the support strap. Furthermore, the size and weight range for the i-gel is printed on the device.

Similar to the LMA, the tip of the i-gel is designed to fit into the proximal esophagus, and the sides and proximal parts of the device form a seal around the hypopharynx. This position facilitates air entry into the trachea (**FIGURE 11-62**). **TABLE 11-13** lists three adult-size i-gel supraglottic airways and patient weight criteria.

The steps for inserting an i-gel supraglottic airway are shown in **SKILL DRILL 11-14**.

The Cobra Perilaryngeal Airway

The **Cobra perilaryngeal airway (CobraPLA)** was first introduced as a device to ventilate patients

with difficult airways. It is so named because of the cobra shape of the distal part of the airway (**FIGURE 11-63**). The shape allows the device to slide easily along the hard palate and to hold the soft tissue away from the laryngeal inlet (hence, *perilaryngeal*) when in place. It is a supraglottic device with a tube for ventilation and a circumferential cuff (that sits in the hypopharynx at the base of the tongue) proximal to the distal end, which is the ventilation outlet. It also has a 15-mm standard adapter, and the distal widened end holds soft tissue apart and allows ventilation of the trachea. The distal tip is proximal to the esophagus and seals the hypopharynx. When the cuff is inflated, it raises the tongue and creates an airway seal allowing for ventilation. Because the insertion technique is simple, it is possible to successfully place the device with minimal or no experience.

TABLE 11-13 Sizes and Patient Criteria for Adult i-gel Supraglottic Airway

Size	Connector Color	Weight Criteria
3	Yellow	66–132 lb (30–60 kg)
4	Green	110–198 lb (50–90 kg)
5	Orange	>198 lb (>90 kg)

Data from: i-gel user guide, 9989 issue 1 01.10, Intersurgical Ltd website. http://docsinnovent.com/downloads/i-gel_User_Guide_English.pdf. Accessed February 21, 2017.

Skill Drill 11-14 Inserting an i-gel Supraglottic Airway

Step 1

Take standard precautions.

Step 2

Lubricate the back, sides, and front of the cuff with a thin layer of water-soluble gel.

Step 3

Preoxygenate the patient before insertion. Do not interrupt ventilation for more than 30 seconds to accomplish airway placement. Place the patient in the sniffing position.

Step 4

Open the airway with the tongue-jaw lift maneuver and position the i-gel so that the cuff outlet is facing toward the patient's chin.

Step 5

Introduce the leading soft tip of the i-gel into the patient's mouth, directing it toward the hard palate.

Step 6

Glide the i-gel downward and backward along the hard palate with a continuous but gentle push until a definitive resistance is felt.

Skill Drill 11-14 Inserting an i-gel Supraglottic Airway (continued)

Step 7

Begin to ventilate the patient. Confirm chest rise and the presence of breath sounds. Ensure proper tube placement with waveform capnography. Continuously and carefully monitor the patient's condition.

Step 8

Secure the i-gel in place with the provided strap.

FIGURE 11-63 The Cobra perilaryngeal airway.

Reproduced from Sunder RA, Sinha R, Agarwal A, Perumal BCS, Paneerselvam SR. Comparison of Cobra perilaryngeal airway (CobraPLATM) with flexible laryngeal mask airway in terms of device stability and ventilation characteristics in pediatric ophthalmic surgery. Journal of Anaesthesiology, Clinical Pharmacology. 2012;28(3):322-325. doi:10.4103/0970-9185.98324.

The CobraPLA is available in eight sizes. Proper size is determined by the one that comfortably fits through the patient's mouth.

Indications and Contraindications for the CobraPLA

The CobraPLA is used in a manner similar to other supraglottic airways and can be used on pediatric patients. Because the device does not provide

protection against aspiration, it is recommended for use only in patients who are not at risk of vomiting.

Contraindications include risk for aspiration and massive trauma to the oral cavity.

Complications of the CobraPLA

If the patient has an intact gag reflex, laryngospasm may occur. If the Cobra is not inserted far enough, inflation of the cuff may cause the tongue to protrude from the mouth, disrupting an adequate seal. Using the proper size is vital because the patient cannot be ventilated if the device is too small and passes into the laryngeal inlet. However, in such an instance, it can be removed and another size inserted with minimal trauma to the oropharynx.

Insertion Technique

To insert the CobraPLA, fully deflate the cuff and apply a water-soluble gel to the front and back of the device and to the cuff. With the patient's head in the sniffing position, open the airway with the tongue-jaw lift maneuver and direct the distal end

of the CobraPLA straight back between the tongue and hard palate. Continue advancing the Cobra-PLA until modest resistance is felt (**FIGURE 11-64A**). Inflate the cuff with only enough air to achieve a good seal; do not overinflate the cuff. Ventilate the patient while observing for chest rise and auscultating over the neck, chest, and epigastrium. Use a detection device for further confirmation and secure the device in place (**FIGURE 11-64B**).

FIGURE 11-64 **A.** Open the airway with the tongue-jaw lift maneuver and advance the Cobra perilyngeal airway until modest resistance is felt. **B.** Inflate the cuff with only enough air to achieve a good seal. Ventilate the patient, confirm proper placement, and secure the device in place.

© Jones & Bartlett Learning.

Multilumen Airway Devices

Combitube

The **Combitube** is a **multilumen airway device** with a long tube that is inserted blindly into the airway (**FIGURE 11-65**). It is a reasonable alternative to ET intubation and has been clinically proven to secure the airway and allow for better ventilation than a bag-mask device and simple airway adjunct in most cases.

In contrast with single-lumen airways, the tube can be used for ventilation whether it is inserted into the esophagus or trachea. Although this device almost always comes to rest in the esophagus, it can function as an ET tube if inserted into the trachea (**FIGURE 11-66**). The Combitube contains two lumens, which function appropriately based on tube position and ventilating through the correct lumen. Each lumen has a standard 15/22-mm ventilation adapter, which accommodates any ventilation device (such as a bag-mask device or mechanical ventilator). The proper port for ventilation depends on where the tube is located. It also contains an oropharyngeal balloon, which eliminates the need for a mask seal.

The major advantage of the multilumen airway is that, in effect, it cannot be improperly placed; effective ventilation is possible whether the tube enters the esophagus or the trachea. Furthermore, because insertion of the airway is performed with the patient's head in the neutral position, cervical spine movement is kept to a minimum.

The Combitube also provides some patency to the airway. If the tube is placed in the trachea, it allows the airway to be maintained, and no upper airway positioning is required. If the tube is placed

FIGURE 11-65 A Combitube.

© Jones & Bartlett Learning.

FIGURE 11-66 **A.** If the Combitube is inserted into the esophagus, then ventilations can still be provided to the patient. **B.** If the Combitube is inserted into the trachea, then it functions as an ET tube, with ventilations provided directly into the trachea.

© Jones & Bartlett Learning.

into the esophagus (as most commonly occurs), the pharyngeal balloon creates an airtight seal in the oropharynx, making the tongue position less of a factor in the maintenance of a patent airway. A jaw-thrust maneuver should easily alleviate any ventilatory difficulty that occurs if the epiglottis partially obstructs the airway.

Use of the Combitube requires strict attention and good assessment skills because ventilation in the wrong port results in no pulmonary ventilation. Multilumen airways are usually considered temporary airways and should be replaced as soon as possible. The pharyngeal balloon reduces, but does not completely eliminate, the risk of aspiration.

Indications and Contraindications for the Combitube

The Combitube is indicated for the airway management of deeply unresponsive, apneic patients with no gag reflex in whom ET intubation is not possible or has failed.

The Combitube cannot be used in pediatric patients younger than 16 years, and it should be used only for patients between 5 and 7 feet (1.5 to 2 m) tall. (A smaller version of the Combitube, called the Combitube SA [small adult], can be used for patients between 4 and 5.5 feet [approximately 1 to 2 m] tall.) Because most of the time the tube is inserted into the esophagus, the Combitube should not be used in patients with a known pathologic condition of the esophagus (such as esophageal varices), patients with esophageal trauma, patients who have ingested a caustic substance, or patients who have a history of alcoholism.

Complications of the Combitube

The most significant complication associated with the use of a Combitube is unrecognized displacement of the tube into the esophagus. (It is acceptable if the tube is placed in the esophagus, but you must realize this to effectively ventilate.) Therefore, good assessment skills are essential to properly confirm tube placement, and use rigorous confirmation protocol following insertion of the device.

Laryngospasm, vomiting, and possible hypoventilation may occur during insertion of a Combitube. Trauma to the pharynx or esophagus may also result from improper insertion technique.

Ventilation may be difficult if the pharyngeal balloon pushes the epiglottis over the glottic opening. In such cases, ventilation should become easier if the device is withdrawn 1 to 1.5 inches (2 to 4 cm).

Insertion Techniques

The Combitube consists of a single tube with two lumens, two balloons, and two ventilation ports.

One of the lumens is open at its distal end, and the other is closed. The closed lumen has side holes distal to the pharyngeal balloon. The proximal balloon is designed to be inflated with 100 mL of air and provide a pharyngeal seal. The distal balloon is inflated with 15 mL of air and makes an airtight seal with the walls of the trachea (in case of tracheal placement) or provides esophageal obturation (in case of esophageal placement).

Before inserting the Combitube, check and prepare all equipment. Check both cuffs and ensure that they hold air. The patient should be preoxygenated before insertion. Ventilation should not be interrupted for longer than 30 seconds to accomplish airway placement. For insertion, the patient's head should be placed in the neutral position.

- **Forwardly displace the jaw.** With the patient's head in the neutral position, insert the thumb of your gloved nondominant hand into the patient's mouth and lift the jaw. This action lifts the hyoid bone and pulls the base of the tongue off the posterior pharyngeal wall.
- **Insert the device.** Following the curvature of the tube, insert the device blindly into the posterior pharynx. The Combitube is inserted until the incisors are between the two black lines printed on the tube. Be gentle, and stop advancing the tube if you meet resistance.
- **Inflate the cuffs.** The Combitube has two independent inflation valves that must be inflated sequentially. The first inflation valve goes to the pharyngeal balloon (on the blue No. 1 tube) and is inflated with 100 mL of air (this is printed on the pilot balloon). The second inflation valve inflates the distal balloon (on the clear No. 2 tube) and is filled with 15 mL of air.

Remember that when inserting a multilumen airway, confirmation of ventilation is very critical. If you used the wrong port, the patient would receive no pulmonary ventilation and you could be instilling air directly into the stomach.

Following inflation of the balloons, begin to ventilate the patient. With the Combitube, ventilate the longer (blue) tube. Confirm the patient's chest rise and the presence of breath sounds. If there are no breath sounds, the chest does not rise and fall with ventilation, or epigastric sounds are present, switch immediately to the other inflation

port. Be sure to continuously monitor ventilation. The Combitube is generally secure in the airway because of the large pharyngeal balloon; however, it is still important to secure the device in place after ventilations are confirmed.

Words of Wisdom

Prior to and during placement of an ET tube, consider applying a nasal cannula and setting the flow rate at 15 L/min. This initiates the processes of preoxygenation and denitrogenation. **Denitrogenation** attempts to replace alveolar nitrogen with oxygen; the goal is to increase oxygen reserve in the lungs, thus minimizing the risk of oxygen desaturation during periods of forced apnea that will occur during the intubation attempt.

Assisting With ALS Airway Procedures

Many AEMTs work as a team with a paramedic partner. When a critical patient needs ET intubation, the paramedic will perform the skill, but the AEMT partner will play an essential role in helping set up for the procedure, performing basic life support airway and ventilation maneuvers, and helping to monitor the patient.

Assisting With Placement of Advanced Airways

ET intubation, as mentioned previously, is the insertion of a tube into the trachea to maintain and protect the airway. The ET tube can be inserted through the mouth or through the nose. In either case, the ET tube passes directly through the larynx between the vocal cords and then into the trachea.

Patient Preparation

The first step in preparing a patient for ET intubation is preoxygenation. The more oxygen that is available in the alveoli, the longer the patient can maintain adequate gas exchange in the lungs while the intubation procedure is being performed (**FIGURE 11-67**).

In all cases, even if the patient is in cardiac arrest or is otherwise not breathing at all, maintain a high-flow nasal cannula on the patient during the

FIGURE 11-67 A. Alveolar-capillary exchange. Oxygen-rich air enters the alveoli, where it crosses into the bloodstream. Carbon dioxide leaves the blood and enters the alveoli. **B.** Capillary cellular exchange. Throughout the body, carbon dioxide from the cells enters the capillaries, and oxygen leaves the capillaries and enters the cells. Carbon dioxide is returned to the lungs in red blood cells (25%), in the form of bicarbonate (69%), and dissolved in blood (6%).

© Jones & Bartlett Learning.

preoxygenation phase and leave the nasal cannula in place during the intubation attempt, a period of time when bag-mask ventilation and chest rise and fall is not possible. This technique, called **apneic oxygenation**, allows for continuous oxygen delivery down the airways during all phases of the intubation procedure.

Equipment Setup

Equipment varies depending on local protocols, provider preference, and whether **direct laryngoscopy** or **video laryngoscopy** will be used. (Direct laryngoscopy is visualization of the vocal cords with a laryngoscope, while video laryngoscopy is visualization of the vocal cords using a video camera and monitor.) These differences emphasize why it is important for team members to train and practice together. Typically, intubation equipment sets include:

- Personal protective equipment, including appropriate face mask and eye shield
- Suction unit with rigid, tonsil-tip (Yankauer) and nonrigid, whistle-tip (French) catheters
- Laryngoscope handle and blade (sized for the patient)
- Magill forceps

- ET tube (sized for the patient)
- Stylette or tube introducer (**gum elastic bougie**)
- Water-soluble lubricant
- 10-mL syringe
- Confirmation device or devices, including waveform $ETCO_2$ monitors and/or colorimetric device
- Commercial ET tube securing device
- Alternate airway management devices, such as a supraglottic airway and/or cricothyrotomy kit

Performing the Procedure

Although the details of ET intubation may vary depending on available equipment, difficulties encountered, and provider preference, you can remember the six typical steps by using the BE MAGIC mnemonic:

- **B** Perform *bag*-mask preoxygenation.
- **E** *Evaluate* for airway difficulties.
- **M** *Manipulate* the patient.
- **A** *Attempt* first-pass intubation.
- **GI** Use a supraglottic or *Intermediate* airway if unable to intubate.
- **C** *Confirm* successful intubation/ *Correct* any issues.

FIGURE 11-68 One AEMT or the paramedic may prepare the intubation equipment while another AEMT continues to ventilate and preoxygenate the patient.

Bag-Mask Preoxygenation

As discussed previously, it is crucial that you adequately preoxygenate the patient before the intubation attempt, especially critical patients (**FIGURE 11-68**). Do not hyperventilate the patient during the preoxygenation phase. This may cause gastric distention and increase the risk of aspiration. Hyperventilation may also cause hypotension. Focus on maintaining a good seal, achieving chest rise and fall, and delivering breaths at a rate appropriate for the patient's age (1 breath every 6 seconds for an adult, and 1 breath every 2 to 3 seconds for an infant or child).

Evaluate for Airway Difficulties

While you preoxygenate the patient, the paramedic should evaluate the patient to identify any factors that will present difficulties during the procedure—for example, trauma or anatomic deformities to the airway. It is crucial that difficulties be identified before the procedure begins. You may assist with this process, as well as the preparation of any equipment that will be needed to address the problem or problems.

Manipulate the Patient

Before the procedure can begin, position the patient so that the paramedic can visualize the vocal cords. Use towels, blankets, and/or pillows to ramp, position, and otherwise manipulate the patient so that the first attempted intubation will be successful. The ideal position is achieved when the patient's ear canal is on the same horizontal plane

FIGURE 11-69 The sniffing position: Position the patient so that the ear canal is on the same horizontal plane as the sternal notch.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Special Populations

It may be difficult for the paramedic to visualize the vocal cords in bariatric and pediatric patients or patients with suspected cervical spine injuries. It may be necessary to open (undo) a cervical collar to perform intubation. As the cervical collar is opened, you may be asked to maintain cervical spine immobilization while the paramedic attempts intubation. Good communication and coordination between team members is critical during these advanced procedures.

as the sternal notch, known as the sniffing position (**FIGURE 11-69**).

Attempt Intubation

When the paramedic is ready to begin the intubation attempt, remove the oral airway and disconnect the mask from the bag in preparation for connecting the bag to the ET tube. Always keep the mask and airway within reach in case the first attempt is unsuccessful and you need to ventilate the patient with the bag-mask device once more. Likewise, keep suction equipment at hand in case you need to suction the patient's airway. The paramedic will begin by inserting the laryngoscope blade into the patient's mouth and will use it to move structures in the airway, such as the tongue and epiglottis, to gain a view of the vocal cords through which the ET tube will pass (**FIGURE 11-70**).

FIGURE 11-70 The paramedic will use the laryngoscope blade to visualize the target of the vocal cords through which the ET tube will pass.

FIGURE 11-71 The cuff of the ET tube must pass through the vocal cords.

Courtesy of James P. Thomas, MD (voicedoctor.net).

FIGURE 11-73 Ensure the ET tube does not move while it is being secured or at any point during patient care.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

The paramedic may ask you for assistance in manipulating the patient's larynx (external laryngeal manipulation) or otherwise positioning the patient for a better view (**FIGURE 11-71**).

Supraglottic or Intermediate Airway

Should the intubation attempts fail, it may be your responsibility to prepare and hand over the supraglottic or intermediate airway device.

Words of Wisdom

The paramedic may place an oral airway back into the patient's mouth after a successful intubation attempt to prevent the patient from biting down on the ET tube.

Confirm Intubation and Correct Issues

If the intubation procedure appears successful, then work with your team to confirm intubation success. You may attach the waveform ETCO_2 detector in line between the ET tube and the bag. You may also either ventilate the patient while another provider checks for positive breath sounds in the absence of gastric sounds, or you may listen while another team member ventilates (**FIGURE 11-72**). A successfully intubated patient should have a waveform ETCO_2 waveform measurement, bilateral breath sounds present and gastric (or epigastric) sounds should be absent. Either absence of breath sounds or presence of gastric sounds suggests the ET tube was improperly inserted into the esophagus. If the intubation is confirmed as successful, then you may assist in securing the ET tube (**FIGURE 11-73**). If the

intubation cannot be confirmed, or if the ET tube appears to be properly placed but airway or breathing issues remain, then you may assist other team members in correcting these issues.

Words of Wisdom

The position of the ET tube is unstable until the tube is secured with tape or a mechanical device. One provider should hold the ET tube in place until it is secured to ensure it is not dislodged by movement at this point in the procedure, or at any time during patient care.

Continuing Care

Once an intubation attempt has been confirmed as successful, the job of airway management is not over for the EMS team. You must continue to observe all of the patient's monitor readings, as well as monitor for signs of potential complications, including:

- **Absence of an end-tidal CO_2 level.** Alert team members if the end-tidal CO_2 waveform suddenly disappears. (This is a sign the ET tube may have shifted out of the proper position.)
- **Decreasing SpO_2 level.** Alert team members if the SpO_2 level begins to decrease, especially below 95%. (This is a sign the ET tube may have shifted out of the proper position.)
- **Increasing resistance when ventilating.** The person assigned the task of ventilation should monitor for increasing resistance when the bag is squeezed for ventilation. When increasing resistance is felt, it could indicate a critical airway or breathing problem that must be addressed, such as the advanced airway device has been mistakenly placed into the esophagus rather than into the trachea, referred to as **esophageal intubation**. When the ET tube is placed in the esophagus, ventilation results in air being pumped into the stomach, which

FIGURE 11-74 Centimeter markings on the ET tube are used to ensure insertion to the appropriate depth.

© American Academy of Orthopaedic Surgeons.

increases the size of the patient's stomach and leads to gastric distention.

- **Other physical signs of poor ventilation and perfusion.** Physical signs include pale skin and cyanosis.
- **Improper positioning or dislodgement of the ET tube.** Each time the patient is moved, it is important to reassess the placement of the ET tube. Verify proper ET tube position by ensuring breath sounds are present, gastric sounds are absent, an end-tidal CO_2 waveform is visible during ventilation, SpO_2 values are stable or rising, and the ET tube is secured at the proper depth marking (**FIGURE 11-74**).

Words of Wisdom

The DOPE mnemonic is often used to troubleshoot problems with an ET tube:

- D** Displaced, dislodged, or damaged tube
- O** Obstructed tube (secretions, blood, mucus, vomitus)
- P** Pneumothorax
- E** Equipment failure (kinked tubing, empty oxygen supply, ventilator malfunction)

YOU are the Provider SUMMARY**1. How does the body regulate ventilation?**

The respiratory system must be able to accommodate the changes in oxygen demand by altering the rate and depth of ventilation. For most people, the drive to breathe is based on pH changes (related to the carbon dioxide level) in the blood and CSF. In healthy people, when the oxygen level rises, the respiratory center suspends respiration until a rising carbon dioxide level stimulates the respiratory center to begin breathing again.

2. What are some of the factors that affect pulmonary ventilation?

There are many factors that affect pulmonary ventilation, both intrinsic and extrinsic. Intrinsic causes include infections, allergic reactions, and airway obstructions (primarily due to tongue occlusion). Extrinsic factors include trauma or foreign body airway obstructions. The most common cause of obstruction in an unresponsive patient is the tongue obstructing the airway.

3. Which acid-base disorder do you suspect this patient is experiencing?

This patient is most likely experiencing respiratory acidosis as a result of his ineffective ventilation. The acidosis that results is quick and overwhelming, making it impossible for the slower-reacting renal system to compensate in time for the pH shift; this results in potentially fatal cardiac dysrhythmia and is usually fatal. Signs and symptoms of respiratory acidosis include vasodilation, headaches, central nervous system depression, bradypnea, nausea, and vomiting.

4. How does the pulse oximeter guide your treatment of this patient?

A pulse oximeter measures the percentage of hemoglobin saturation. Under normal conditions, the SpO_2 should be 98% to 100% while breathing room air. An SpO_2 of 94% or lower generally requires treatment unless the patient has a chronic condition causing

a perpetually low oxygen saturation. Although the pulse oximeter should not directly guide your treatment, it can be used as a confirmatory adjunct that will confirm the patient's hypoxic state and give a numeric display as to the effectiveness of your interventions.

5. What are the indications for insertion of an advanced airway?

Indications for insertion of an advanced airway include deeply unresponsive, apneic patients without an intact gag reflex and patients in whom ET intubation is not possible or has been unsuccessful.

6. What are the contraindications for insertion of a King LT airway?

As with other advanced airway devices, contraindications for insertion of a King LT airway include responsive patients with an intact gag reflex, patients with known esophageal disease, and patients who have ingested caustic substances.

7. What are some possible respiratory patterns you may encounter?

Some of the possible respiratory pattern changes that you may encounter include Cheyne-Stokes respirations, Biot respirations, Kussmaul respirations, central neurologic hyperventilation, and agonal gasps. Any changes in respiratory pattern indicate a seriously ill patient and warrant aggressive airway management.

8. If the patient's respiratory rate increases to an acceptable level, should the King LT airway be removed?

The decision of whether to remove an advanced airway after it is inserted should be made in accordance with local protocols and consultation with medical direction. Typically, if a patient regains consciousness and is able to maintain their own airway adequately, the advanced airway can be removed, provided that a suction device is readily available at the patient's bedside.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 7-22-20	Incident No.: 56712	Nature of Call: Respiratory distress		Location: 421 Golden Acres Lane

Engine 9938 dispatched to above location, room 107, for man with respiratory distress. On arrival, met by patient care attendant, Stephanie, who states patient was admitted to facility earlier this AM and is breathing "funny." Patient presents with initial GCS of 7 (E-1, V-2, M-4), respirations of 6-8 breaths/min, cyanosis present around lips and nail beds. Bag-mask ventilations established at a rate of 10/min, O₂ administered at 15 L/min. Initial Spo₂ of 78%. Unable to get history from PCA; only information she is able to provide is that the patient is a "full code." Firefighter Hollister states she is having poor compliance with bag-mask ventilations due to patient's dentition. Prepared patient for insertion of King LT. After establishing patency, head aligned, size 5 King LT inserted without difficulty. Balloon inflated with 80 mL. Placement confirmed with clear bilateral breath sounds, equal/adequate chest rise, and increasing Spo₂. Dispatch contacted for transporting ambulance ETA. Made contact with paramedics, who advise quick ETA. On arrival of paramedics, report given, care released.

End of report

Prep Kit

Ready for Review

- The respiratory system includes the diaphragm, the muscles of the chest wall, and the accessory muscles of breathing.
- The upper airway includes the nose, mouth, jaw, oral cavity, pharynx, and larynx. Its function is to warm, filter, and humidify air as it enters the nose and mouth.
- The lower airway includes the trachea and lungs, and its function is to exchange oxygen and carbon dioxide.
- The respiratory system and the renal system have roles in maintaining a balance between acids and bases in the body. The respiratory system works to quickly remove excess acid as carbon dioxide from the lungs. Conversely, slowing respirations will increase carbon dioxide. The renal system regulates pH by filtering out more hydrogen and retaining bicarbonate when needed, or doing the reverse.
- Adequate breathing features a normal rate of 12 to 20 breaths/min, a regular pattern of inhalation and exhalation, bilateral clear and equal lung sounds, regular and equal chest rise and fall, and adequate tidal volume.
- Inadequate breathing for an adult features a respiratory rate of fewer than 12 breaths/min or more than 20 breaths/min; shallow depth (reduced tidal volume); an irregular pattern of inhalation and exhalation; and breath sounds that are diminished, absent, or noisy.
- Patients who are breathing inadequately show signs of hypoxia, a dangerous condition in which the body's tissues and cells do not have enough oxygen.
- Patients with inadequate breathing need to be treated immediately. Emergency medical care includes airway management, supplemental oxygen, and ventilatory support.
- Clearing the airway means removing obstructing material; maintaining the airway means keeping it open.
- Basic techniques for opening the airway include the head tilt–chin lift maneuver and the jaw-thrust maneuver.
- Suctioning is the next priority after opening the airway. Rigid tonsil-tip catheters are the best to use when suctioning the pharynx; soft, plastic catheters are used to suction the nose and liquid secretions in the back of the mouth. AEMTs may also need to perform tracheobronchial suctioning in patients who have been intubated by paramedics.
- One basic airway adjunct is the oropharyngeal or oral airway, which keeps the tongue from blocking the airway in unresponsive patients with no gag reflex. If the oral airway is not the proper size or is inserted incorrectly, it can push the tongue back into the pharynx, causing an obstruction.
- Another basic airway adjunct is the nasopharyngeal or nasal airway, which is usually used with patients who have a gag reflex and is better tolerated than the oral airway.
- The recovery position is used to help maintain the airway in patients without traumatic injuries who are breathing adequately on their own.
- You must provide immediate artificial ventilations with supplemental oxygen to patients who are not breathing on their own. Patients with inadequate breathing may also require artificial ventilations to maintain effective tidal volume.
- Handle compressed gas cylinders very carefully; their contents are under pressure. Always make sure the correct pressure regulator is firmly attached before transporting a cylinder. The pin-indexing safety system features a series of pins on a yoke that must be matched with the holes on the valve stem of the gas cylinder. Pressure regulators reduce the pressure of gas in an oxygen cylinder to between 40 and 70 psi. Pressure-compensated flowmeters and Bourdon-gauge flowmeters permit the regulated release of gas measured in liters per minute.
- When oxygen therapy is complete, disconnect the tubing from the flowmeter nipple, and turn off the cylinder valve; then turn off

the flowmeter. As long as there is a pressure reading on the regulator gauge, it is not safe to remove the regulator from the valve stem. Keep any possible source of fire away from the area while oxygen is in use.

- Nasal cannulas and nonrebreathing masks are used most often to deliver oxygen in the field. The nonrebreathing mask is the delivery device of choice for providing supplemental oxygen to patients who are breathing adequately but are suspected of having or are showing signs of hypoxia. With a flow rate set at 15 L/min and the reservoir bag preinflated, the nonrebreathing mask can provide more than 90% inspired oxygen. If the patient will not tolerate a nonrebreathing mask, apply a nasal cannula.
- Pulse oximetry, an assessment tool to evaluate the effectiveness of oxygenation, does not take the place of a good assessment. This measurement depends on adequate perfusion to the capillary beds and is inaccurate when the patient is cold or in shock or has been exposed to carbon monoxide.
- The methods of providing artificial ventilation include mouth-to-mask ventilation, one-person bag-mask device ventilation, two-person bag-mask ventilation, and the MTV device. The MTV device is not a recommended ventilation device by most standards. Your own exhaled breath combined with high-flow oxygen at 15 L/min through the oxygen inlet valve will give your patient up to 55% oxygen; a bag-mask device with an oxygen reservoir and supplemental oxygen can deliver nearly 100% oxygen.
- CPAP is a noninvasive method of providing ventilatory support for patients in respiratory distress or suffering from sleep apnea.
- It is imperative to be familiar with indications, contraindications, advantages, disadvantages, and special considerations when choosing the appropriate device. This is especially important when dealing with pediatric patients. Regardless of the method, aggressive airway management is essential to a positive patient outcome.
- When you are providing artificial ventilation, remember that ventilating too forcefully can cause gastric distention. Slow, gentle breaths during artificial ventilation can help to prevent

gastric distention. Patients who have a tracheal stoma or a tracheostomy tube need to be ventilated through the tube or the stoma.

- Check for loose dental appliances in a patient before assisting ventilation. Loose appliances should be removed to prevent them from obstructing the airway. Tight-fitting appliances should be left in place.
- Airway problems can be especially challenging in patients with serious facial injuries. Control bleeding with direct pressure and suction as necessary.
- Foreign body airway obstruction usually occurs during a meal in an adult or while a child is eating, playing with small objects, or crawling about the house. The earlier you recognize any airway obstruction, the better. You must learn to recognize the difference between airway obstruction caused by a foreign object and that caused by a medical condition.
- Foreign body airway obstructions are classified as being mild or severe. Patients with a mild airway obstruction are able to move adequate amounts of air and should be left alone. Patients with a severe airway obstruction cannot move any air at all and require immediate treatment. Perform abdominal thrusts on a responsive adult or child with a severe airway obstruction. If the patient becomes unresponsive, begin CPR with high-quality chest compressions, and attempt to ventilate the patient.
- Advanced devices that can be used by AEMTs to provide definitive airway management to patients unable to maintain their own airway include esophageal airways and multilumen airways.
- The King LT is a single-lumen airway that is blindly inserted into the esophagus. When it is properly placed in the esophagus, the distal cuff seals the esophagus while the proximal cuff seals the oropharynx. Openings located between these two cuffs provide for ventilation of the lungs.
- The LMA is designed to provide a conduit from the glottic opening to the ventilation device. When properly inserted, the opening of the LMA is positioned right at the glottic

opening. The inflatable cuff conforms to the contours of the airway and makes a relatively airtight seal.

- The Cobra perilaryngeal airway is designed to slide easily along the hard palate and to hold the soft tissue away from the laryngeal inlet when in place. The distal tip is proximal to the esophagus and seals the hypopharynx. When the cuff is inflated, it raises the tongue and creates an airway seal allowing for ventilation.

- Multilumen airways have two tubes and can be inserted blindly. The Combitube is an example of such a device. A multilumen airway can be used to ventilate via the esophagus or the trachea based on placement.
- As an AEMT, you may assist a paramedic partner with airway skills beyond the AEMT scope of practice. You will play an essential role in helping set up for the procedure, performing BLS airway and ventilation maneuvers, and helping to monitor the patient

Vital Vocabulary

acidosis A pathologic condition that results from the accumulation of acids in the body; an increase in extracellular H^+ ions; a blood pH of less than 7.35.

aerobic metabolism The metabolism that takes place in the presence of oxygen.

agonal gasps Occasional gasps that are ineffective attempts at breathing, occurring after the heart has stopped.

airway The upper airway tract or the passage above the larynx, which includes the nose, mouth, and throat, and the lower airway, which includes the trachea and lungs. Also used to refer to devices used to open and maintain a patient's airway.

alkalosis A pathologic condition resulting from the accumulation of bases in the body; a decrease in extracellular H^+ ions; a blood pH greater than 7.45.

alveolar minute volume The volume of air moved through the lungs in 1 minute minus the dead space; calculated by multiplying tidal volume (minus dead space) and respiratory rate.

alveolar ventilation The volume of air that reaches the alveoli. It is determined by subtracting the amount of dead space air from the tidal volume.

American Standard System A safety system for oxygen cylinders larger than size E, designed to prevent the accidental attachment of a regulator to a cylinder containing the wrong type of gas.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the principal product is lactic acid.

anoxia An absence of oxygen.

apnea Absence of breathing; periods of not breathing.

apneic oxygenation A technique in which oxygen administered via a high-flow nasal cannula is left in place during an intubation attempt, allowing for continuous oxygen delivery into the airways during all phases of the procedure.

aspiration The introduction of vomit or other foreign material into the lungs.

asymmetric chest wall movement Unequal movement of the two sides of the chest; indicates decreased airflow into one lung.

ataxic respirations Irregular, ineffective respirations that may or may not have an identifiable pattern.

atelectasis A condition of airless or collapsed alveoli that causes pulmonary shunting, ventilation-perfusion mismatching, and possibly hypoxemia.

automatic transport ventilator (ATV) A mechanical ventilator that is used to ventilate intubated patients during transport; has settings for the tidal volume and ventilatory rate.

bag-mask device A device with a face mask attached to a ventilation bag containing a reservoir and connected to oxygen; delivers more than 90% supplemental oxygen.

barrier device A protective item, such as a pocket mask with a valve, that limits exposure to a patient's body fluids.

bilateral In anatomy, a body part or condition that appears on both sides of the midline.

bilevel positive airway pressure (BPAP) A form of noninvasive positive-pressure ventilation that delivers two pressures (a higher inspiratory positive airway pressure and a lower expiratory positive airway pressure).

Bourdon-gauge flowmeter An oxygen flowmeter that is commonly used because it is not affected by gravity and can be placed in any position.

bradypnea Slow respiratory rate; ominous sign in a child; indicates impending respiratory arrest.

bronchioles Fine subdivisions of the bronchi made of smooth muscle that give rise to the alveolar ducts.

capnographer A device that attaches between the endotracheal tube and ventilation device; provides graphic information about the presence of exhaled carbon dioxide.

capnometer A device that performs the same function and attaches in the same way as a capnographer but provides a digital reading of the exhaled carbon dioxide.

carina Point at which the trachea bifurcates (divides) into the left and right main stem bronchi.

cellular respiration A biochemical process resulting in the production of energy in the form of adenosine triphosphate.

chemoreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in chemical composition of the blood to help maintain homeostasis.

Cobra perilaryngeal airway (CobraPLA) A supraglottic airway device with a shape that allows the device to slide easily along the hard palate and to hold the soft tissue away from the laryngeal inlet.

colorimetric carbon dioxide detector A device that attaches between the endotracheal tube and ventilation device; uses special paper that should turn from purple to yellow during exhalation, indicating the presence of exhaled carbon dioxide.

Combitube A dual-lumen airway device that is inserted blindly; permits ventilation of the patient whether the tube is placed in the esophagus or the trachea.

continuous positive airway pressure (CPAP) A method of ventilation used primarily in the treatment of critically ill patients with respiratory distress; can prevent the need for endotracheal intubation.

dead space The amount of inhaled air that does not participate in respiration.

denitrogenation The process of replacing nitrogen in the lungs with oxygen to maintain a normal oxygen saturation level during advanced airway management.

direct laryngoscopy Visualization of the airway with a laryngoscope.

dorsal respiratory group A portion of the medulla oblongata where the primary respiratory pacemaker is found.

dyspnea Shortness of breath or difficulty breathing.

endotracheal (ET) intubation Insertion of an endotracheal tube directly through the larynx between the vocal cords and into the trachea to maintain and protect an airway.

end-tidal carbon dioxide (ETCO₂) monitor A detection device for monitoring the amount of carbon dioxide in exhaled air that can be used to adjust oxygen administration or ventilations.

esophageal intubation Improper placement of an advanced airway device into the esophagus rather than into the trachea.

exhalation The part of the breathing process in which the diaphragm and the intercostal muscles relax, forcing air out of the lungs.

expiration The process of moving air out of the lungs.

external respiration The exchange of gases between the lungs and the blood cells in the pulmonary capillaries; also called pulmonary respiration.

gag reflex A normal reflex mechanism that causes retching; activated by touching the soft palate or the back of the throat.

glottic opening The narrowest portion of the adult's airway; space between the vocal cords.

gum elastic bougie A flexible device that is inserted between the glottis under direct laryngoscopy; the endotracheal tube is threaded over the device, facilitating its entry into the trachea.

head tilt–chin lift maneuver A combination of two movements to open the airway by tilting the forehead back and lifting the chin; used for non-trauma patients.

Hering-Breuer reflex The protective nervous system mechanism that terminates inhalation and prevents lung overexpansion.

hypercapnia Increased carbon dioxide level in the bloodstream.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal; may lead to increased intrathoracic pressure, decreased venous return, and hypotension when associated with bag-mask device use.

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

hypoxemia A deficiency of oxygen in arterial blood.

hypoxia A dangerous condition in which the body's tissues and cells do not have enough oxygen.

hypoxic drive A backup system that controls respirations by sensing when the oxygen level in the blood falls.

i-gel A supraglottic airway device that uses a noninflatable, gel-like mask to isolate the larynx and facilitate ventilation.

inhalation The active, muscular part of breathing that draws air into the airway and lungs; a medication delivery route; in allergic reactions, breathing in foreign substances through the respiratory system.

inspiration The process of moving air into the lungs.

internal respiration The exchange of gases between the blood cells and the tissues.

intrapulmonary shunting Bypassing of oxygen-poor blood past nonfunctional alveoli to the left side of the heart.

jaw-thrust maneuver Technique to open the airway by placing the fingers behind the angle of the jaw and bringing the jaw forward; used when a patient may have a cervical spine injury.

ketoacidosis An acidotic state created by the production of ketones via fat metabolism.

King LT airway A single-lumen airway that is blindly inserted into the esophagus; when properly placed in the esophagus, one cuff seals the esophagus, and the other seals the oropharynx.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and characterized by grunting, stridor, and use of accessory muscles; occurs when air movement is impaired.

laryngeal mask airway (LMA) An airway device that is inserted into the mouth blindly and comes to rest at the glottic opening. A flexible cuff is inflated, creating an almost airtight seal.

laryngectomy A surgical procedure in which the larynx is removed.

laryngospasm The spasmodic contraction of the vocal cords, accompanied by an enfolding of the arytenoid and aryepiglottic folds.

larynx A complex structure formed by the epiglottis, thyroid cartilage, cricoid cartilage, arytenoid cartilage, corniculate cartilage, and cuneiform cartilage; the voice box.

lung compliance The ability of the alveoli to fully expand when air is drawn in during inhalation.

manually triggered ventilation (MTV) device A fixed flow rate ventilation device that delivers a breath every time its button is pushed; also referred to as a flow-restricted, oxygen-powered ventilation device.

mediastinum The space between the lungs, in the center of the chest, that contains the heart, trachea, large blood vessels, main stem bronchi, part of the esophagus, lymphatic channels, and paired vagus and phrenic nerves.

metabolic acidosis A pathologic condition characterized by a blood pH of less than 7.35 and

caused by accumulation of acids in the body from a metabolic cause.

metabolic alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a metabolic cause.

metabolism The chemical processes that provide the cells with energy from nutrients.

mild airway obstruction A condition in which an obstruction leaves the patient able to exchange some air, but also causes some degree of respiratory distress.

minute volume The amount of air moved in and out of the respiratory tract (minus the dead space) per minute; determined by the tidal volume multiplied by the respiratory rate. Also called minute ventilation.

multilumen airway device A type of airway device with a single long tube that can be used for esophageal obturation or endotracheal tube ventilation, depending on where it comes to rest following blind positioning.

nasal cannula An oxygen-delivery device in which oxygen flows through two small, tubelike prongs that fit into the patient's nostrils.

nasopharyngeal (nasal) airway An airway adjunct inserted into the nostril of a responsive patient who is not able to maintain a natural airway.

negative-pressure ventilation Drawing of air into the lungs; airflow from a region of higher pressure (outside the body) to a region of lower pressure (the lungs); occurs during normal (unassisted) breathing.

nonbreathing mask A combination mask and reservoir bag system that is the preferred way to give oxygen in the prehospital setting; delivers up to 90% inspired oxygen.

oropharyngeal (oral) airway An airway adjunct inserted into the mouth to keep the tongue from blocking the upper airway and to make suctioning the airway easier.

orthopnea Severe dyspnea experienced when lying down that is relieved by a change in position, such as sitting up or standing.

oxygenation The process of delivering oxygen to the blood by diffusion from the alveoli following inhalation into the lungs.

oxygen saturation (Spo₂) The measure of the percentage of oxygen molecules that are bound to hemoglobin in arterial blood.

oxygen toxicity A condition of excessive oxygen consumption resulting in cellular and tissue damage.

paradoxical motion The inward movement of the chest during inhalation and outward movement during exhalation; the opposite of normal chest wall movement during breathing; occurs in a flail chest.

parietal pleura The thin membrane that lines the pleural (chest) cavity.

partial laryngectomy Surgical removal of a portion of the larynx.

partial pressure The term used to describe the amount of gas in air or dissolved in fluid, such as blood.

partial rebreathing mask A mask that is similar to a nonbreathing mask except there is no one-way valve between the mask and the reservoir; therefore, patients rebreathe a small amount of their exhaled air.

patent Open, clear of obstruction.

phrenic nerve The nerve that innervates the diaphragm; necessary for adequate breathing.

pin-indexing system A system established for portable cylinders to ensure that a regulator is not connected to a cylinder containing the wrong type of gas.

pneumothorax A partial or complete accumulation of air in the pleural space.

positive end-expiratory pressure (PEEP) Mechanical maintenance of pressure in the airway at the end of expiration to increase the volume of gas remaining in the lungs.

preload The precontraction pressure in the heart, which increases as the volume of blood builds up when returned to the heart (venous return); directly affects afterload.

preoxygenation The process of providing oxygen, often in combination with ventilation, prior

to intubation in order to raise the oxygen levels of body tissues; a critical step in advanced airway management. This extends the time during which an advanced airway can be placed in an apneic patient, because the more oxygen that is available in the alveoli, the longer the patient can maintain adequate gas exchange in the lungs during the procedure.

pulmonary edema A buildup of fluid in the lungs, usually as a result of left-side heart failure.

pulse oximetry An assessment tool that measures oxygen saturation of hemoglobin in the capillary beds.

recovery position A side-lying position used to maintain a clear airway in unresponsive patients who are breathing adequately and do not have suspected injuries to the spine, hips, or pelvis.

residual volume The air that remains in the lungs after a maximal expiration.

respiration The inhaling and exhaling of air; the physiologic process that exchanges carbon dioxide from fresh air; also, the exchange of gases that occurs at the pulmonary and cellular levels.

respiratory acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by accumulation of acids in the body from a respiratory cause such as inadequate ventilation.

respiratory alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a respiratory cause such as overaggressive ventilation.

respiratory rate The number of ventilatory cycles in a unit of time, usually 1 minute; also known as the ventilation rate.

retractions Movements in which the skin pulls in around the ribs during inspiration; the drawing in of the intercostal muscles and the muscles above the clavicles that can occur in respiratory distress.

severe airway obstruction Occurs when a foreign body completely obstructs the patient's airway. Patients cannot breathe, talk, or cough.

stoma A surgical opening in the body that connects an internal structure to the skin, such as

in the neck to connect the trachea directly to the skin.

stridor A harsh, high-pitched breath sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

suction catheter A hollow, cylindrical device used to remove fluids and secretions from the airway.

surfactant A liquid protein substance that coats the alveoli in the lungs, decreases alveolar surface tension, and keeps the alveoli expanded, allowing for easy expansion and recoil of the alveoli; a low level in a premature baby contributes to respiratory distress syndrome.

tachypnea Rapid respiratory rate.

tidal volume The amount of air (in milliliters) that is moved into or out of the lungs during one relaxed breath; approximately 500 mL for an adult.

tongue-jaw lift maneuver A method of opening the airway for suctioning or inserting an oral airway; involves grasping the incisors or gums and lifting the jaw.

tonsil-tip catheter A suction catheter with a large, semirigid suction tip, recommended for suctioning the pharynx; also called Yankauer tip.

total laryngectomy Surgical removal of the entire larynx.

trachea The windpipe; the main conduit for air passing to and from the lungs.

tracheostomy Surgical creation of a hole in the trachea.

tracheostomy tube A tube inserted through the hole created by a tracheostomy, used to facilitate breathing.

turbinates Bony shelves that extend from the lateral walls of the nose into the nasal passageway; increase the surface area of the nasal mucosa, improving filtration, warming, and humidification of inhaled air.

vasodilatory shock A type of shock related to relaxation of the blood vessels, allowing blood to pool and impairing circulation.

ventilation The exchange of air between the lungs and the air of the environment, spontaneously by the patient or with assistance.

ventral respiratory group A portion of the medulla oblongata that is responsible for modulating breathing during speech.

video laryngoscopy Visualization of the vocal cords, and thereby placement of the endotracheal tube that is facilitated by use of a video camera and monitor.

visceral pleura Thin membrane that covers the lungs.

vital capacity The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.

$\dot{V}/\dot{Q}$ mismatch A measurement that examines how much gas is being moved effectively and how much blood is gaining access to the alveoli.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Pharmacology

12 Principles of Pharmacology

13 Vascular Access and Medication Administration

SECTION

5

Chapter 12

Principles of Pharmacology

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Pharmacology

Applies (to patient assessment and management) fundamental knowledge of the medications carried by AEMTs that may be administered to a patient during an emergency.

Principles of Pharmacology

- Medication safety (p 637)
- Kinds of medications used during an emergency (p 639)
- Medication legislation (pp 640–641)
- Naming (p 639)
- Classifications (p 641)
- Storage and security (p 643)
- Autonomic pharmacology (p 646)
- Metabolism and excretion (pp 646–654)
- Mechanism of action (pp 645, 662–663)
- Medication response relationships (p 664)
- Medication interactions (pp 664–665)
- Toxicity (p 638)

KNOWLEDGE OBJECTIVES

1. Discuss important drug terminology, including intended effects, unintended effects, untoward effects, indications, and contraindications. (pp 638–639)
2. Discuss the differences between generic, trade, chemical, and official medication names, and provide an example of each. (p 639)
3. Discuss the US laws and regulations that relate to medication manufacturing and distribution. (p 640)
4. List the five schedules of drugs with the highest abuse potential per the Controlled Substances Act. (p 641)
5. Discuss the US Food and Drug Administration (FDA) approval process. (pp 642–643)
6. Describe the proper storage for drugs and security concerns. (p 643)
7. Describe the medication administration considerations that must be applied to special populations, including pediatric, geriatric, and pregnant patients. (pp 643–645)
8. Discuss legal, moral, and ethical considerations related to drug administration. (p 645)
9. Explain the term mechanism of action. (pp 645, 662–663)
10. Describe the roles and functions of the sympathetic and parasympathetic nervous systems. (p 646)
11. Discuss the concept of receptor sites, including adrenergic receptors, and how medications may take advantage of these. (pp 646–647)
12. Discuss the concepts of agonists and antagonists as they relate to medications. (pp 647–648)

13. List the types of drugs that affect the sympathetic nervous system, including sympathomimetics and sympatholytics, and describe how they create their effects. (pp 646–647)
14. List the types of drugs that affect the parasympathetic nervous system, including parasympathomimetics and parasympatholytics, and describe how they create their effects. (pp 648–649)
15. Discuss the effects of opioid agonists, opioid antagonists, and opioid agonist-antagonists. (pp 649–650)
16. Discuss types of sedative-hypnotics, including benzodiazepines, barbiturates, nonbarbiturate hypnotics, and dissociative anesthetic agents. (p 650)
17. Discuss central nervous system stimulants and depressants. (p 651)
18. Discuss drugs that affect the cardiac system, including cardiac glycosides, antidysrhythmics, and antihypertensive medications, and describe how they exert their effects. (pp 651–653)
19. Describe drugs that affect the respiratory system, including oxygen, over-the-counter medications, bronchodilators, and xanthines. (p 653)
20. Explain the solid, liquid, and gas forms of medication; provide examples of each; and discuss how the form of a medication dictates its route of administration. (pp 654–658)
21. Describe the enteral and parenteral routes of medication administration and explain how they differ. (p 658)
22. Describe the following routes of medication administration and discuss their individual rates of absorption: oral, intravenous, intraosseous, subcutaneous, intramuscular, sublingual, intranasal, and inhalation. (pp 658–659)
23. Define the term pharmacokinetics and describe the stages a medication goes through while being processed in the body. (pp 659–661)
24. Define the term pharmacodynamics and describe the types of predictable and unpredictable responses a drug may create. (pp 662–663)
25. Discuss the concepts of serum sickness, idiosyncratic reaction, cumulative effect, summation, potentiation, drug dependence, and medication interaction. (pp 664–665)
26. Give the generic and trade names, actions, indications, contraindications, routes of administration, side effects, interactions, and doses of at least 10 medications and 3 intravenous fluids that may be administered by an AEMT in an emergency as directed by state protocols and local medical direction. (pp 668–677)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

Administering medications is a serious business. Used appropriately, medication may alleviate pain, ease suffering, and improve a patient's well-being. However, used inappropriately, medication may cause harm and even death. *All medications are poisons if they are given to the wrong patient or in toxic quantities.* As an advanced emergency medical technician (AEMT), you will be responsible for administering certain medications to patients and helping them to self-administer others. You will ask patients about their medication allergies, and you will report this information to hospital personnel. To act without understanding how medications work will place both patients and you in danger.

This chapter describes the various forms of medications, the different ways in which they can be administered, and their mechanisms of action. It then takes a close look at each of the forms of medications you may be called on to administer or help patients to self-administer.

TABLE 12-1 lists components of a drug profile and serves as an introduction to the type of information covered in this chapter. A drug profile gives all specifics about the drug. This is the information included on the package insert and listed in various pharmaceutical publications. As an AEMT, you should familiarize yourself with the drug profiles of the medications you may be expected to administer.

TABLE 12-1 Components of a Drug Profile

Drug names—This includes the generic name, trade name, and chemical name.

Classification—What type of drug is this? What is it used for?

Mechanisms of action—How does the drug work? What is its intended purpose?

Indications—What are the reasons for taking this drug?

Contraindications—When should the drug not be given? Does it affect certain medical conditions or react with other medications adversely?

Pharmacokinetics—How is the drug absorbed, metabolized, and so forth? What is its **half-life**?

Side and adverse effects—Are there any side effects? What are the adverse effects?

Routes of administration—How is the drug given?

How supplied—What is the total quantity of the medication? What form?

Dosages—This generally includes proper dosages for adult, pediatric, and special considerations, such as when to modify the dosage based on the patient's history.

Special considerations—These are considerations for certain groups such as pediatric, geriatric, and pregnant patients and other special patient groups.

Other—The drug profile may include any other information that is vital to the user.

© Jones & Bartlett Learning.

Drug Terminology

Pharmacology is the study of the properties (characteristics) and effects of drugs and medications on the body. **Drugs** are substances that produce a physiologic effect, whether therapeutic or not; clinically, they are chemical agents used in the diagnosis, treatment, and prevention of disease. Although the terms *drugs* and *medications* are often used interchangeably, the word *drugs* may make some people think of narcotics or illegal substances. For this reason, you should try to use the word *medications*, especially when interviewing patients and families. In general terms, a **medication** is a chemical substance that is used to treat or prevent disease or relieve pain.

The **dose** of the medication is the amount that is given. The dose depends on the patient's size and age; adults and children may receive different amounts of the same medication. The dose also depends on the desired action of the medication. The **action** is the therapeutic effect or **intended effect** that a medication is expected to have on the body. For example, nitroglycerin relaxes the walls of the blood vessels and may dilate the arteries. This effect increases the blood flow and, thus, the supply of oxygen to the heart muscle. In this way, nitroglycerin relieves the squeezing or crushing pain that occurs with angina. Nitroglycerin is therefore indicated for chest pain associated with angina. **Unintended effects** are the effects that are undesirable but pose little risk to the patient. **Untoward effects** are the effects that can be harmful to the patient. **Toxicity** is the risk that a substance will pose a health hazard to an individual or organism.

Indications are the therapeutic uses for a particular medication. There are times when you should

YOU are the Provider

Part 1

Your ambulance is dispatched to a man lying unresponsive in an alley. On arrival, you find a law enforcement officer leaning over a man who is in his mid 30s. The patient is unresponsive and not breathing. The officer has opened the airway, is providing ventilations with a pocket mask, and states that the patient is well known to him and has an extensive history of intravenous (IV) drug use, with his drug of choice being heroin.

1. Are there any potential hazards with this scene?
2. What medication might the AEMT carry that would be appropriate to administer in this situation?

Words of Wisdom

An indication is a reason for giving a drug. A contraindication is a reason not to give a drug. The number one contraindication for most medications is hypersensitivity (allergy) to that drug.

not give a patient medication, even if it usually is indicated for that person's condition. Such situations are called **contraindications**. A medication is contraindicated when it would harm the patient or have no positive effect on the patient's condition. For example, administration of oral glucose is indicated when a patient has a low blood glucose level. Because of the high sugar content, it rapidly raises blood glucose levels. However, oral glucose is contraindicated if patients are unresponsive and could not swallow or had an altered mental status and could not maintain their airway.

Medication Names

The medications we use are derived from four principal sources: animal, vegetable, mineral, and synthetic compounds. Plant sources of medications include a variety of roots, leaves, flowers, and seeds. For example, digitalis, which is used in the treatment of heart failure, is prepared from the dried leaves of a wildflower called purple foxglove. In contrast, insulin, a medication taken by diabetic patients, is usually prepared from the pancreas of animals (primarily pigs). Minerals used in the treatment of medical problems include calcium, iron, and magnesium. Drugs that are manufactured synthetically include synthetic forms of vitamins, steroids, narcotics, and many others.

Medications have different types of names. A **trade name** is the brand name that a manufacturer gives to a medication, such as Tylenol and Lasix. As a proper noun, a trade name begins with a capital letter. Trade names are used in every aspect of our daily lives, not just in medications. Well-known examples include Jell-O gelatin, Band-Aid adhesive bandages, and Hershey's chocolate candy. A medication may have many different trade names, depending on how many companies manufacture it. Advil, Nuprin, and Motrin all are trade names for the same generic medication, ibuprofen.

The **generic name** of a medication (such as ibuprofen) is usually its original chemical name, which is not capitalized, and is usually suggested by the first manufacturer and approved by the US Food and Drug Administration (FDA). Sometimes a medication is called by its generic name more often than by any of its trade names. For example, you may hear the term *nitroglycerin* used more often than the trade names Isordil and Nitrostat. All medications that are licensed for use in the United States are listed by their generic names in the *United States Pharmacopeia (USP)*.

The **chemical name** of a medication is a precise description of the drug's chemical composition and molecular structure. The **official name** is the name assigned by the USP. In most cases, the official name is generally the generic name followed by "USP."

Examples of the four names for a drug are as follows:

- **Chemical name:** 9-chloro-11 β ,17,21-trihydroxy-16 β -methylpregna-1,4-diene-3,20-dione 17,21-dipropionate
- **Generic name:** beclomethasone dipropionate
- **Trade name:** Vanceryl
- **Official name:** beclomethasone dipropionate, USP

Medications may be **prescription medications** or **over-the-counter (OTC) medications**. Only pharmacists, according to a physician's order, can legally distribute prescription medications to patients. However, OTC medications may be purchased directly from a wholesale or retail source, such as a discount store or supermarket, without a prescription. In recent years, the number of prescription medications that have become available OTC has increased dramatically. Therefore, many of the problems attributable to prescription medications may become more common. You may also come in contact with patients who have taken street drugs such as heroin or cocaine. Although street drugs lack the pharmaceutical purity of OTC or prescribed medications, they are still pharmacologically active and will cause an effect.

Sources of Drug Information

There are numerous references to learn more about a specific drug. Information regarding drugs can also be obtained by using a hospital formulary—a

local publication that delineates which drugs are used in a particular facility. Medications come packaged with drug inserts that give information specific to preparation, dosage, effects, possible **side effects**, and other information. There are also numerous other texts and sources, including the Internet. AEMTs should be familiar with these resources and other field references, particularly regarding medications commonly encountered in the prehospital setting. **TABLE 12-2** lists some of the most up-to-date and reliable sources.

US Regulation of Pharmaceuticals

The manufacture of pharmaceuticals in the United States and most other countries is subject to a variety of laws and regulations. The goal of these laws and regulations is to protect consumers. In particular, they prohibit manufacturers from making false claims about the benefits of their drugs and prohibit companies from advising patients on the administration of the drugs, which may be incorrect. These laws also seek to protect patients from drugs

that might cause harm and require drug manufacturers to publish information about side effects and known potential harmful effects of their products. Note that these laws do not prevent physicians from prescribing drugs for reasons that are not consistent with the FDA-approved labeling. Such decisions are common when the physician explains the relative risks and benefits of the proposed off-label use to the patient.

Laws and regulations also outline standards for drug manufacture to ensure that drugs produced by different manufacturers are uniform in strength and purity. In the United States, these drug standards are published in the *USP* and the *National Formulary*. In addition, several federal laws have been enacted to protect consumers (patients) from unsafe substances and unscrupulous manufacturers and distributors.

Drug-Related Legislation

The Pure Food and Drug Act (1906) was the first federal legislation in the United States aimed at protecting the public from mislabeled, poisonous, or otherwise harmful foods, medications, and

TABLE 12-2 Sources of Drug Information	
Source	Description
US FDA Center for Drug Evaluation and Research	Mission is to ensure that safe and effective drugs are available in the United States.
<i>Physicians' Desk Reference</i>	Compiles data on most medications available in the United States; uses the information on file with the FDA; includes all necessary information on indications, dosages, contraindications, and adverse reactions. The size of the book made it difficult for use on an ambulance, but the newer smartphone app version makes it more accessible in the field.
Hospital formulary	A list of drugs, dosage forms, package sizes, and drug strengths stocked by hospitals and pharmacies; published as a quick reference to assist the physician and nursing staffs; divided into four general sections: introduction, therapeutic index, drug monographs, and general reference.
Drug inserts	Printed document included in the packaging provided by the drug's manufacturer; generally the same information submitted and approved by the FDA; when available, serves as a valuable reference; should not be confused with the information provided by a pharmacy when a patient receives a prescription, which is useful in obtaining information pertaining to a drug but is not necessarily all inclusive.

Abbreviation: FDA, Food and Drug Administration
© Jones & Bartlett Learning.

alcoholic beverages. It required little more than the labeling of drugs, and it was replaced by more comprehensive legislation in 1938.

The Food, Drug, and Cosmetic Act (1938, amended in 1952 and 1962) added several new provisions:

- Required drug makers to label their products, indicating whether they contain potentially habit-forming substances and to include warnings about possible side effects
- Authorized the creation of the FDA, discussed later in this chapter
- Mandated that dangerous drugs could be dispensed only with a prescription from a physician, dentist, or veterinarian

The Harrison Narcotic Act (1914) regulated the import, manufacture, prescription, and sale of several nonnarcotic drugs and cocaine, opium, and their derivatives. Precise record keeping about the dispensing of controlled drugs and registration of distributors, such as pharmacists, are required. Penalties—namely, fines and imprisonment—are specified for illegal possession or distribution of controlled drugs.

The Narcotic Control Act (1956) increased the penalties for violation of the Harrison Act, made the possession of heroin illegal, and outlawed the acquisition and transportation of marijuana.

In 1970, Congress enacted the Controlled Substances Act, comprehensive legislation dealing with narcotic and nonnarcotic drugs that have potential for abuse. This act specifies requirements for registration, procurement, storage, distribution, and record keeping for these drugs and penalties for failure to comply with these requirements. The drugs covered by the Controlled Substances Act are classified into five categories, or *schedules*, according to their abuse potential. Schedule I includes drugs with the highest abuse potential, and Schedule V includes drugs with the lowest abuse potential. **TABLE 12-3** lists these schedules, including descriptions and examples.

Schedule I drugs have the highest abuse potential and a propensity for severe **drug dependence**; none of them have any accepted medical application. In general, Schedule I drugs are completely outlawed. On rare occasions, and under the strictest control by the FDA and Drug Enforcement Agency

(DEA), these drugs may be used for research, analysis, and instruction only.

Some states have enacted their own laws or regulations related to the use, storage, and handling of controlled substances. If the state law is more stringent than the federal law, the state law takes precedence.

Although marijuana is still a Schedule I narcotic, most states, including the District of Columbia, have legalized marijuana for certain medical purposes, and almost one-half have made marijuana fully legal, including for recreational use.¹ The laws regarding the use of medical marijuana and the types of medical conditions for which its use is allowed vary from state to state. As an AEMT, you should be aware of the laws in your state and always follow local protocols.

TABLE 12-3 Classification of Medications Considered Controlled Substances

Schedule	Description	Examples
I	High abuse potential; no recognized medical purpose	Heroin, marijuana, LSD
II	High abuse potential; legitimate medical purpose	Fentanyl (Sublimaze), methylphenidate (Ritalin), cocaine
III	Less potential for abuse than Schedule II medications	Hydrocodone (Vicodin), acetaminophen with codeine (Tylenol #3 with codeine), ketamine
IV	Less potential for abuse than Schedule III drugs	Diazepam (Valium), lorazepam (Ativan)
V	Less potential for abuse than Schedule IV drugs	Narcotic cough medicines

Abbreviation: LSD, lysergic acid diethylamide

© Jones & Bartlett Learning.

Words of Wisdom

Although the use of marijuana has been legalized in most states, it is important to remember that it is still federally classified as a Schedule I drug.

Manufacturing-Related Regulations

Federal legislation also focuses on guaranteeing standardization of doses. Standardization assures patients that when they take a medication with a stated amount of the active ingredient, they will, in fact, receive that amount of the drug. Clearly, no one would want to be prescribed a certain dose of a drug and find that the actual medication contained twice (or one-half) the amount of active ingredient stated on the drug's label. For a drug to have the USP label, the amount of active ingredients must be within 95% to 105% of that stated on the label. For example, if the label says "300 mg of amiodarone," the medication must contain between 285 and 315 mg of the drug.

Government Agencies That Regulate Drugs

Today, regulation of drugs in the United States falls under the jurisdiction of several agencies:

- The FDA enforces the Food, Drug, and Cosmetic Act. As part of its responsibilities, the FDA is charged with determining the safety and efficacy of drugs before they are allowed to enter the US market. The FDA also holds the regulatory oversight authority regarding the safety and effectiveness of vaccines used in the United States.
- The DEA, formerly the Bureau of Narcotics and Dangerous Drugs, was created by the Federal Controlled Substances Act of 1970. The DEA, which is a division of the Justice Department, is responsible for executing the provisions of the Controlled Substances Act, including the registration of physicians who are permitted to dispense controlled substances.

- The Federal Trade Commission (FTC) monitors drug advertising and ensures that it is not misleading or inappropriate. The FTC has become involved in making recommendations to the FDA regarding direct-to-consumer (DTC) advertisements. The FTC found that DTC advertisements "generally benefit consumers" but stated that DTC ads should contain a "major statement of drug risks along with adequate provision for more complete risk information."

The Drug-Approval Process

New drugs are constantly being developed. The commercialization process, however, takes years—the average time for a drug to be developed, tested, and approved is approximately 9 years. In some cases, manufacturers spend most of those 9 years developing a drug only to find out that the drug does not work as envisioned or is too dangerous for human consumption.

All new drugs must go through animal studies and clinical trials in humans before they are approved for distribution.

Animal Studies

Animal studies are designed to learn more about the properties of a drug and to identify tissues and organs that are sensitive to the actions of the drug. Testing in at least two animal species is required by law. After successful completion of animal studies, an investigational new drug may enter clinical trials in humans.

Clinical Trials

Clinical trials proceed in four phases:

- **Phase I.** The new drug is tested in healthy volunteers to compare human data with those in animals to determine safe doses of the drug and to assess its safety.
- **Phase II.** These trials are performed in homogeneous populations of patients (50 to 300 patients). In double-blind studies, one group receives the drug and the other group receives a placebo. These studies are designed to evaluate the efficacy and safety of the drug and to establish which form is the most effective dose.

- **Phase III.** In these clinical trials, the drug is made available to a larger group of patients (several thousand). These studies, which usually last several years, evaluate the efficacy of the drug and monitor the nature and incidence of side effects.
- **Phase IV.** After successful completion of Phase III clinical trials, the drug company can apply to the FDA for approval to market the drug. Phase IV trials compare the new drug with others on the market and examine the drug's long-term efficacy and cost-effectiveness.

Drug Storage and Security of Controlled Substances

All drug containers or “boxes” should be carefully guarded against possible theft. This requires that the boxes not only be locked, but also secured within the ambulance. Your local protocols will determine the manner in which the drugs are maintained, including how they are secured, stored, distributed, and accounted for.

If controlled substances, such as narcotics, are administered, the records must be kept separate from other paperwork. As mentioned earlier, the DEA strictly regulates these substances. If drugs are

lost or stolen, the supervisor and law enforcement personnel must be notified immediately.

All medications should be stored in an environment with a constant temperature if possible. Temperature, light, moisture, shelf life, and exposure to air all affect the potency of medications. If controlled medications are not used before their expiration dates, they must be destroyed. The destruction must be witnessed by two employees and documented on the proper forms.

Special Considerations in Drug Therapy

Pregnant Patients

Before you administer any medications to a female of childbearing age, the patient should be asked whether she could possibly be pregnant. In an emergency situation, the health of the woman is the priority. However, before using any drug during pregnancy, the expected benefits should be considered against the possible risk to the fetus. Drugs, whether prescription or OTC, have the potential to harm the fetus by crossing the placental barrier, as well as through lactation. A **teratogenic** drug is one that poses a risk to the normal development or health of the unborn fetus.

YOU are the Provider

Part 2

You quickly assess the scene for hazards. Finding none, you begin your assessment. You find no obvious trauma, but note fresh needle track marks on the patient's left arm. Assessment of the eyes reveals slightly reactive pupils that are constricted bilaterally. You believe that your patient is experiencing an acute narcotic overdose and prepare a dose of naloxone. You direct your partner to insert an oropharyngeal airway and begin assisting ventilations with a bag-mask device.

Recording Time: 1 Minute

Appearance	Unresponsive
Level of consciousness	Unresponsive
Airway	Patent
Breathing	Assisted at 10 breaths/min
Circulation	Strong radial pulse, skin is warm and dry

3. By which route or routes may naloxone be administered?
4. What class of medication is naloxone?

Changes in a pregnant woman's body also affect the way drugs are processed and may increase the chance of harm to the fetus. Metabolism of drugs in the liver is decreased during pregnancy, along with an increased rate of excretion owing to increased cardiac output.

The FDA has removed the scale with the categories A, B, C, D, and X to indicate drugs that have documented problems in animals and/or humans during pregnancy. This five-category system has been replaced by a more detailed system that uses narrative summaries to convey prescribing information related to pregnancy (including labor and delivery), lactation, and the risks of a medication to male and female users with reproductive potential. Medications approved after June 2015 have only the narrative summary.^{2,3} This change was driven by concerns that the five-category system oversimplified risks related to pregnancy and lactation, resulting in poor prescribing decisions.² Labels are updated as information changes and becomes outdated. **TABLE 12-4** outlines the type of information provided in the narrative summary.

Many drugs used with unknown effects during pregnancy are still used. For this reason, it is better

to delay pharmacologic treatments for pregnant patients until they reach the hospital, except in life-threatening situations.

In the field, you must be able to quickly evaluate the risks versus the benefits of drug administration. Does the potential benefit to the pregnant woman outweigh the risk to the fetus? If the drug is the only option for saving the woman's life, then that consideration would be paramount. When in doubt, contact medical control to discuss the situation.

Pediatric Patients

Medications have different effects in adults than they do in children—whether the pediatric patient is a newborn, a neonate, an infant, or a toddler. Young infants have a sharply reduced metabolic capacity. The incomplete development of the gastrointestinal tract in young infants slows **absorption** of oral medications and delays elimination, so the same medication may be more potent in an infant than in an adult.

However, children can metabolize some medications much more quickly than adults do, so they may require relatively higher doses or more frequent administration of some medications. Also, the products of metabolism in children can vary from those seen in adults, which may sometimes result in unexpected responses.

TABLE 12-4 Drug Categories for Pregnant Women	
Drug Categories (Pregnancy, Lactation, and Reproductive Potential)^a	Type of Information in Narrative Summary
Pregnancy (includes labor and delivery)	Pregnancy exposure registry Risk summary Clinical considerations Data
Lactation (includes nursing mothers)	Risk summary Clinical considerations Data
Female and male users with reproductive potential	Pregnancy testing Contraception Infertility

Special Populations

When you are treating pediatric patients, it is imperative to remember that they are not just little adults. Medication dosage is usually based on a child's weight or body surface area as opposed to age because size varies greatly from child to child. If possible, determine the exact weight of the child by asking the parent or guardian. With infants and toddlers, a length-based resuscitation tape works well for estimating and also gives accurate dosage information for most emergency drugs and sizes for endotracheal tubes and IV catheters.

When you are treating neonates, it is important to remember that they have immature body systems and are unable to metabolize drugs as quickly as an older child or adult can. Medications tend to remain in the system for longer periods, resulting in lengthened times of drug effect. Dosages may need to be altered to prevent inadvertent overdose.

Geriatric Patients

The changes in pharmacokinetics in geriatric patients are comparable to those observed in young children. In elderly people, hepatic functions and gastrointestinal activity slow, which delays absorption and elimination. In addition, geriatric patients are often taking several medications; these concomitant therapies may interact and modify the effects of each medication. Furthermore, because geriatric patients may take many medications and may have alterations in their normal mental status, geriatric patients may unintentionally overdose on a particular drug or forget to take it.

Scope of Practice

As an AEMT, you are legally, morally, and ethically responsible for each drug you administer. You must have a good foundation of knowledge of OTC and prescription medications that may interact with drugs you may give, and you must have enough knowledge to obtain a medical history for patients who are unable to communicate.

Drug administration must be safe and therapeutically effective. You should always keep a field guide or other medication reference handy to look up medications that are unfamiliar to you. Follow the standardized national guidelines listed in **TABLE 12-5** when providing drug therapy.

Words of Wisdom

If available, use a scale present at the scene (eg, patient's home, daycare center, doctor's office) to get an accurate weight for the patient prior to administering a weight-based medication.

Methods of Drug Classification

Classifications of drugs are based on the effect the drugs will have on a particular part of the body or on a specific condition. Antiemetic medications, for example, suppress the sensation of nausea. Many medications fall into more than one classification. For example, promethazine (Phenergan) is

TABLE 12-5 Guidelines for Providing Drug Therapy

Understand pharmacology.
Use correct precautions and techniques.
Observe and document the effects of drugs, good or bad.
Obtain a drug history from patients, including prescribed medications (name, strength, and daily dosage), over-the-counter medications, vitamins, herbal preparations, and drug reactions. If possible, gather all medications to take along to the hospital with the patient.
Perform an evaluation to identify drug indications and contraindications.
Establish and maintain professional relationships.
Keep your knowledge base current for changes and trends in pharmacology.
Seek drug reference literature.
Consult with medical direction.

an antiemetic and an antihistamine. This section discusses a few of the classifications of drugs and their subcategories.

Drugs or medications can be classified into the following three categories:

- **By body system.** Classification by body system is simply categorizing by the system affected by that drug. Nitroglycerin is a vasodilator that is used predominantly for cardiac ischemia; therefore, it is classified as a cardiac drug. Understanding which systems are affected by which drugs will help you make the appropriate decisions for patient care.
- **Class of agent.** The class of a medication tells how it affects the system. For example, an antipyretic is given to reduce fever, and an antiemetic is used to control vomiting.
- **Mechanism of action.** The mechanism of action is the particular action by which the drug creates its desired effect on an organism. Again, using the example of nitroglycerin, it is a potent vasodilator given for cardiac ischemia because it opens the vessels to allow oxygenated blood to pass through.

Nervous System Classifications

The nervous system is the body's principal control system. It is composed of the central nervous system (CNS), made up of the brain and spinal cord, and the peripheral nervous system, which includes all nervous tissue outside the CNS. (See Chapter 7, *The Human Body*, for more about the body's systems.)

Recall that the peripheral nervous system contains the **autonomic nervous system (ANS)**, which controls all of the automatic, or involuntary, functions. The ANS is divided into the sympathetic nervous system and the parasympathetic nervous system. The **sympathetic nervous system** is responsible for the body's response to shock and stress and is known as the fight-or-flight division. This response is associated with the release of adrenaline from the adrenal glands. The sympathetic nervous system response is called **adrenergic** because special adrenergic nerve fibers ultimately cause the release of the hormones epinephrine (adrenaline) and norepinephrine (noradrenaline). Sympathetic responses include shunting of blood from the extremities to the vital core organs, increasing the heart rate and respirations, increasing blood pressure, dilation of the pupils, and reduction of digestive system activity (**FIGURES 12-1** through **12-3**).

The **parasympathetic nervous system** relaxes the body. It controls automatic functions during nonstressful times and is referred to as the rest-and-digest division. Stimulation of the parasympathetic nervous system results in effects opposite from those of the sympathetic nervous system. Heart and respiratory rates decrease, blood pressure lowers,

the pupils constrict, and digestive system activity increases.

The sympathetic and parasympathetic divisions work in constant opposition to each other to maintain basic harmony in the body, with each division taking more precedence in the proper circumstances.

The hormones released by sympathetic system stimulation are carried throughout the body where they cause their intended effects by acting directly on hormone receptors. This stimulates tissues that are not innervated by sympathetic nerves and also prolongs the effects of direct sympathetic stimulation. Adrenergic receptors are located throughout the body and, after stimulation by the appropriate hormone, they cause a response in the target organ. Adrenergic receptors are generally divided into four types **TABLE 12-6**.

Drugs Affecting the Sympathetic Nervous System

To give the best patient care, it is imperative for you to recognize how certain medications affect the body. Drugs can be given that produce the same effects on a body system as the hormones of the sympathetic nervous system that are released naturally in the body. These drugs are known as **sympathomimetics** because they mimic the effects of the sympathetic nervous system. Medications that have the opposite effect, or inhibit the sympathetic nervous system, are known as **sympatholytics** (also known as antiadrenergics), which antagonize, or fight against, the effects of the sympathetic

FIGURE 12-1 Receptor sites of the sympathetic nervous system in the heart, lungs, and arteries.

FIGURE 12-3 Alpha agents have no direct effect on the heart. Alpha-1 agents, which are present on vascular smooth muscle and myocardial tissue, cause marked vasoconstriction when stimulated. Alpha-2 agents, by blocking the release of norepinephrine, can lead to vasodilation.

© Jones & Bartlett Learning.

TABLE 12-6 Alpha and Beta Responses

Type of Receptor	Response
Alpha-1 (α_1)	Peripheral vasoconstriction
Alpha-2 (α_2)	Peripheral vasodilation Little or no bronchoconstriction
Beta-1 (β_1)	Increased heart rate Increased automaticity Increased contractility Increased conductivity
Beta-2 (β_2)	Bronchodilation Vasodilation

© Jones & Bartlett Learning.

nervous system. A drug that counteracts the action of something else is called an **antagonist**, and a drug that binds to a receptor and causes a response is called an **agonist**.

Words of Wisdom

Think of the hormones of the sympathetic nervous system as a key that starts a car. When the key is placed in the ignition (or the hormone is placed in the receptor site) and the key is turned, a certain sequence of events occurs to start the car. If you have a duplicate key made and use it to start the car, the same sequence of events takes place. This is exactly what happens when a sympathomimetic drug (the duplicate key) is introduced into the body. The same sequence of events takes place when the duplicate is joined with the receptor site.

Some medications stimulate alpha and beta receptors, whereas others are selective to specific receptors (**FIGURE 12-4**). A medication that is an agonist of an alpha-1 receptor stimulates the receptor,

FIGURE 12-4 Many sympathomimetic agents have both alpha and beta properties.

© Jones & Bartlett Learning.

FIGURE 12-5 A sympathetic blocker occupies the receptor site for the stimulating drug, thereby preventing the stimulating drug from exerting its usual effect.

© Jones & Bartlett Learning.

causing vasoconstriction of the vessels, thereby increasing blood pressure, cardiac preload, and afterload. When these receptors are antagonized (suppressed), the blood pressure is lowered by preventing vasoconstriction.

Many patients take medications that belong to the **beta-blocker** class. These are used to control blood pressure in some patients and heart rhythm disturbances in others. Beta-blockers work by filling a portion of the beta receptor sites—the portion to which beta stimulators would normally bind (**FIGURES 12-5** and **12-6**). In this way, beta effects are prevented.

Words of Wisdom

Imagine beta-blockers as the plastic plugs that are placed in electric sockets to prevent children from sticking things into the sockets. The plugs do not do anything; they only plug up the holes. Beta-blockers work the same way. They have no effect on the body; they only plug up the receptor sites, preventing beta agonists from binding.

FIGURE 12-6 By occupying beta receptor sites, the beta-blocker prevents epinephrine from exerting its usual effects on the heart, lungs, and blood vessels.

© Jones & Bartlett Learning.

In the prehospital setting, you will often administer drugs that agonize the beta-1 receptors to treat cardiac arrest and hypotension. Stimulation of these receptors increases myocardial contractility. In contrast, antagonizing the beta-1 receptors lowers the blood pressure by limiting the myocardial contractility and the heart rate. It also decreases impulse generation in the heart and slows the conduction at the atrioventricular node, thereby treating tachycardia.

Beta-2-selective drugs cause bronchodilation with little effect on the heart, which only has beta-1 receptor sites. Stimulation of the beta-2 receptors allows you to treat asthma and other diseases that cause excessive narrowing of the bronchioles.

Drugs Affecting the Parasympathetic Nervous System

Like the sympathetic division, agonists to the parasympathetic nervous system are known as

parasympathomimetics and antagonists are known as **parasympatholytics**. One of the most commonly used parasympatholytics is the drug atropine, which is used for symptomatic bradycardia and exposure to organophosphates and certain chemical nerve agents.

Parasympathomimetics are also called **cholinergic** medications because they stimulate the cholinergic receptors, to which acetylcholine (ACh) normally binds. ACh is an important neurotransmitter in the parasympathetic nervous system. Cholinergic medications may act directly or indirectly on cholinergic receptors. A drug that has direct action binds with cholinergic receptors, thereby blocking ACh. If it acts to prevent activation of the receptor by binding, its function is described as **anticholinergic**. A drug that has indirect action interacts with acetylcholinesterase (AChE), which normally deactivates ACh. When a drug interacts with AChE, deactivation of ACh does not occur. If excessive cholinergics are present, the patient may exhibit the SLUDGEM symptoms: increased Salivation/Sweating, Lacrimation (excessive tearing of the eyes), Urination, Defecation/Drooling/Diarrhea, Gastrointestinal upset and cramps, Emesis (vomiting), and Muscle twitching/Miosis (pinpoint pupils). Patients exposed to certain fertilizers, insecticides, VX (a nerve agent), and sarin gas exhibit SLUDGEM symptoms because all of these substances have cholinergic properties.

Parasympatholytics are also called anticholinergic medications; they block the two types of cholinergic receptors (muscarinic and nicotinic).

Muscarinic cholinergic antagonists block ACh exclusively at the muscarinic receptors. Atropine, for example, is a muscarinic cholinergic antagonist; it decreases secretions, increases the heart rate, dilates the pupils, and decreases gastrointestinal system activity. On the other hand, nicotinic cholinergic antagonists block ACh exclusively at the nicotinic receptors. This inhibition effectively disables the ANS, so it is virtually never used.

Analgesics and Antagonists

Analgesics include medications that relieve pain—that is, induce analgesia (the absence of the sensation of pain). Sometimes the analgesic itself is not sufficient to relieve pain, in which case an adjunct medication may be given to enhance the effects of the analgesic.

The most common class of medications used for analgesia in the prehospital setting is opioid agonists. **Opioid agonists**, which are similar to or derived from the opium plant, bind to opiate receptors. By blocking these receptors, they prevent the neurons from sending pain signals.⁴ These medications are also CNS depressants. Fentanyl (Sublimaze) is a popular opioid agonist because it is rapid-acting, is very potent, and has a relatively short **duration of action**. The patient will experience analgesia within approximately 90 seconds, and the drug's effective duration is approximately 30 minutes. Morphine is a popular option for prehospital analgesia. In addition to analgesia, morphine tends to cause a euphoric feeling.

Words of Wisdom

Atropine is a potent *parasympatholytic* that is used to increase the heart rate in symptomatic bradycardia. Because increasing the heart rate is an effect of the sympathetic nervous system, you might think that atropine is classified as a sympathomimetic. However, atropine has no effect on the heart itself. Instead, it acts as a roadblock to the vagus nerve and prevents innervation by ACh. It does not directly affect the target organ, in this case the heart, but prevents anything from passing through. Because it decreases the effects of the parasympathetic nervous system (which slows the heart rate), it is an antagonist to the parasympathetic division, or a parasympatholytic.

Words of Wisdom

A major concern with the use of opioid analgesics is their potential for abuse and addiction. Many patients are first exposed to opioid medications as a result of treatment for an injury or health-related condition associated with pain. They subsequently become addicted and transition to illegal use of opioid drugs, such as heroin, when prescription access to such medications for treatment of a legitimate medical condition ends. By not using opioid analgesics when alternative treatment options exist, such exposure and addiction can be avoided, potentially saving countless lives. Always consider alternatives before administering opioid analgesics to patients.

Several **nonopioid analgesics** exist, many of which are available as OTC drugs. Many of these nonopioid analgesics have antipyretic properties as well, meaning they can reduce the patient's fever. All of these medications alter the production of prostaglandins and cyclooxygenase (COX) to produce their effects. Three forms of nonopioid analgesics are particularly popular: salicylates (such as aspirin), **nonsteroidal anti-inflammatory drugs (NSAIDs)** (such as ibuprofen), and para-aminophenol derivatives (such as acetaminophen [Tylenol]).

The NSAIDs are designed to reduce pain, inflammation, and fever. They work by inhibiting the COX enzymes, which produce the chemical prostaglandin; prostaglandin promotes pain, inflammation, and fever. Aspirin differs slightly from other NSAIDs in that it targets the COX-1 enzymes to reduce platelet aggregation, which provides great benefit in patients who are suspected of experiencing a myocardial infarction by helping to keep clots from forming and propagating. This also explains why you cannot substitute another NSAID such as ibuprofen, which is a nonselective COX inhibitor, for aspirin in this situation.

Opioid antagonists reverse the effects of opioid drugs. They bind with the opiate receptors in an antagonistic manner; as a result of this binding, the opioid molecules cannot get to the receptor, and the receptor cannot initiate its action. The most common opioid antagonist used in the prehospital setting is naloxone (Narcan).

Finally, **opioid agonist-antagonists** have agonistic and antagonistic properties. They are often preferred because they can decrease pain but do not diminish the function of the respiratory system or result in risk of dependence or addiction, unlike some other analgesics.

Antianxiety, Sedative, and Hypnotic Drugs

Drugs that produce sedation are used to help a patient sleep through a medical procedure. To ensure that the patient sleeps through the event, the person also receives drugs that produce hypnosis. Drugs that create sedation and hypnosis include benzodiazepines, barbiturates, opioid agonists, nonbarbiturate hypnotics, and dissociative anesthetic agents. There are currently no drugs in these categories that are within the scope of practice of the AEMT.

Benzodiazepines are the sedatives most commonly used to prepare patients for invasive procedures. Although their exact mechanism of action is not fully understood, these drugs are believed to affect the neurotransmitter gamma-aminobutyric acid (GABA) in the brain. Benzodiazepine molecules bind to a receptor near GABA binding sites, which is thought to enhance their affinity for GABA. This increased affinity causes brain activity to slow. **Barbiturates** are believed to work similarly to benzodiazepines by increasing the affinity between receptor sites and the neurotransmitter GABA.

The **nonbarbiturate hypnotics** have almost identical properties to benzodiazepines and barbiturates in how they affect GABA receptors. The difference is that nonbarbiturate hypnotics tend to have comparatively fewer side effects, particularly regarding cardiovascular compromise.

Dissociative anesthetic agents, such as ketamine, are another category often used as an adjunct to facilitate airway placement in the prehospital environment. The chemical composition is similar to that of phencyclidine, and these drugs cause profound dissociation and general anesthesia. Ketamine can maintain blood pressure and heart rate, but it also raises intracranial pressure, making it less than optimal for patients with head injury who require airway placement. Ketamine also causes some degree of bronchodilation, which may be beneficial for those with respiratory problems requiring airway management. An emergence reaction with brief psychosis, disorientation, hallucinations, and other effects is possible following ketamine administration. Certain providers and settings are using ketamine for control of refractory pain or delirium that is unresponsive to other medications.

Anticonvulsants

A seizure is a state of neurologic hyperactivity. Active seizures generally require treatment in the prehospital setting because of the complications associated with them. Although the exact mechanism behind **anticonvulsant medications** is not completely clear, these drugs are believed to work by inhibiting the influx of sodium into cells. This halt of sodium transport decreases the cells' capability to depolarize and propagate the seizures. Several other types of drugs are used as anticonvulsants,

including benzodiazepines, barbiturates, hydantoins, and valproic acids.

Stimulants

A common group of CNS agents is **stimulants**, which exert their action by excitation of the CNS. The CNS can be stimulated in one of two ways: by increasing excitatory neurotransmitters or by decreasing inhibitory neurotransmitters. Caffeine, cocaine, and amphetamines (prescription and illicit) are examples of CNS stimulants. They increase the release of dopamine and norepinephrine to increase wakefulness and awareness and reduce drowsiness and fatigue. They also increase tachycardia and hypertension and can cause seizures and psychosis. High doses of these agents can cause increased nervousness, irritability, tremors, and headache. Some people may also experience withdrawal symptoms when they stop taking stimulants.

Depressants

In other cases, patients may be prescribed CNS **depressants**. These agents are used to slow brain activity. They may be prescribed to treat anxiety, muscle tension, pain, insomnia, stress, panic attacks, and, in some cases, seizures. Some other CNS depressants are used as anesthetics. Examples of CNS depressants include lorazepam (Ativan), triazolam (Halcion), chlordiazepoxide (Librium), diazepam (Valium), alprazolam (Xanax), and zolpidem tartrate (Ambien).

Psychotherapeutic Drugs

Most psychotherapeutic drugs work by blocking dopamine receptors in the brain. Schizophrenia is often treated with medications that fit into the phenothiazine and butyrophenone classifications. These medications are associated with a host of side effects, which may include extrapyramidal symptoms, orthostatic hypotension, and sedation. They also tend to cause sexual dysfunction. **Extrapyramidal symptoms** include a wide array of symptoms such as involuntary movements, tremors, rigidity, muscle contractions, restlessness, and changes in breathing and heart rate.

Depression is a common disorder for which many treatments are available. In particular, depression is often treated with selective serotonin

reuptake inhibitors and monoamine oxidase inhibitors, which block the metabolism of monoamines in the brain. Although their popularity is waning, tricyclic antidepressants are still occasionally used as antidepressants.

Drugs Affecting the Cardiovascular System

The walls of the heart are composed of many interconnected cells. These cells are specialized to perform particular functions: some conduct electrical impulses; others cause the heart to contract. Medications targeting the cardiovascular system are classified according to their effects on these specialized cells.

The various effects on the heart are categorized as follows. A **chronotropic** effect is one that affects the heart rate. An **inotropic** effect changes the force of contraction. A **dromotropic** effect is when a drug alters the velocity of the conduction of electricity through the heart. All three types of effects can be positive or negative. For example, if there is a positive chronotropic effect, the heart rate has increased. If there is a negative inotropic effect, the heart is not squeezing as forcefully.

Cardiac Glycosides

Cardiac glycosides are a class of medications that are derived from plants. These drugs block certain ionic pumps in the heart cell membranes, which indirectly increases calcium concentrations. However, cardiac glycosides generally have a small therapeutic index (margin of safety) and are associated with numerous side effects.

Antidysrhythmic Medications

Antidysrhythmic medications have long been used in the prehospital setting to treat and prevent cardiac rhythm disorders. These medications can have direct and indirect effects on cardiac tissue. Antidysrhythmics are further classified into the following four groups according to their fundamental mode of action on the heart:

- **Sodium channel blockers** slow the conduction through the heart; in other words, they have a negative dromotropic effect.
- Beta-blockers reduce the adrenergic stimulation of the beta receptors.

- **Potassium channel blockers** increase the heart's contractility (positive inotropy) and work against the reentry of blocked impulses.
- **Calcium channel blockers** block the inflow of calcium into the cardiac cells, thereby decreasing the force of contraction and automaticity. They may also decrease the conduction velocity (negative dromotropic effect).

Antihypertensive Medications

Over 100 million people in the United States have hypertension.⁵ Medications administered to treat hypertension, known as **antihypertensives**, have the following treatment goals: keep blood pressure within normal limits, maintain or improve blood flow, and reduce the stress placed on the heart.

Diuretic medications cause the kidneys to remove excess amounts of salt and water in the body. By lowering the total fluid volume, they reduce the level of stress placed on the cardiovascular system. In particular, diuretics lower the preload on the heart and decrease the stroke volume. **Vasodilator medications** act on the smooth muscles of the arterioles and veins. This property explains why nitroglycerin, a vasodilator, is so beneficial in treating myocardial ischemia. Unfortunately, the dilation of

these vessels prompts a response from the sympathetic nervous system. Consequently, when vasodilators are used to lower blood pressure, the patient must also take medications that inhibit the sympathetic nervous system.

Sympathetic blocking agents include beta-blockers and adrenergic inhibitors. Beta-blockers, mentioned earlier, compete with epinephrine to bind with available receptor sites, thereby diminishing the effects of beta stimulation.

Angiotensin-converting enzyme (ACE) inhibitors target the renin-angiotensin-aldosterone system, which partially controls blood pressure. ACE inhibitors suppress the conversion of angiotensin I to angiotensin II, thereby decreasing blood pressure. Angiotensin II is a potent vasoconstrictor that promotes smooth muscle contraction in the arterioles throughout the body. This constriction raises the blood pressure by increasing peripheral resistance.

Calcium channel blockers, mentioned earlier, have antidysrhythmic and antihypertensive properties. By causing the dilation of coronary arteries, calcium channel blockers enable more oxygen to reach the heart via coronary artery dilation. In addition, they prevent the contraction of smooth vascular muscle, which reduces resistance in the peripheral vascular system.

YOU are the Provider

Part 3

Because you note numerous track marks on the patient's arms and extensive scar tissue, you opt to administer naloxone via the intranasal route. You proceed to draw 0.4 mg of naloxone in a 1-mL syringe, attach your mucosal atomizer device (MAD) to the syringe, and, while instructing your partner to temporarily stop ventilations, inject the medication into the patient's left naris. As soon as you have administered the medication, you instruct your partner to continue ventilations. Knowing that narcotic overdose patients often become combative after the naloxone begins to work, you advise your partner and the law enforcement officer to stay alert for the possibility of a combative patient.

Recording Time: 8 Minutes

Respirations	Assisted at 12 breaths/min
Pulse	Strong and regular, 82 beats/min

Blood pressure	124/66 mm Hg
Oxygen saturation (SpO₂)	100% on 15 L/min via bag-mask device
Pupils	Constricted

5. What is the mechanism of action of naloxone?

Anticoagulants, Fibrinolytics, and Blood Components

Platelets repair damage in the blood vessels. This function is critical because defects in blood vessels can cause blood flow to slow, sometimes enough to result in the formation of a blood clot (also known as a thrombus). Abnormal thrombi may cause a life-threatening crisis such as acute coronary syndrome or stroke. A variety of medications are used to prevent or minimize the detrimental effects of thrombi.

Antiplatelet agents interfere with the aggregation, or collection, of platelets. They do not break down aggregated platelets but simply prevent further buildup of these blood cells. Notably, salicylic acid (aspirin) has substantial antiplatelet properties and has proved important in the prehospital setting because of its ability to minimize the damage to the myocardium in acute coronary syndrome.

Anticoagulant drugs, as their name suggests, work against coagulation, thereby preventing thrombi from forming. Some patients can be prescribed anticoagulants on a long-term basis as a preventive measure, thereby avoiding the formation of thrombi associated with surgeries and certain cardiovascular conditions. You need to be aware of anticoagulant use, particularly when patients have sustained a traumatic injury. Just as anticoagulants prevent blood coagulation in the vascular system, they can also prevent the life-saving coagulation needed to prevent blood loss.

After a blood clot has formed, a **fibrinolytic agent** may be administered to dissolve the thrombus and prevent it from breaking off and entering the bloodstream, where it might do further damage. Fibrinolytic agents promote the digestion of fibrin (the protein involved in forming a blood clot). The use of fibrinolytic medications in the prehospital setting remains controversial, and, in some circumstances, other forms of reperfusion therapy may be indicated.

Drugs Affecting the Respiratory System

Oxygen is the most commonly used medication in the prehospital setting. And it is, in fact, a medication—which means it has appropriate and inappropriate uses and some side effects. Supplementary oxygen therapy is covered in depth in Chapter 11, *Airway Management*.

Patients may be taking a gamut of medications to treat respiratory problems, depending on their symptoms. Especially during the cold and influenza seasons, use of OTC decongestant medications is common. Patients may also take antihistamines during allergy season. Try to find out which medications your patient is taking, and know the effects that these drugs may have on other medications and the signs and symptoms they can produce. Although each decongestant varies slightly in its mechanism of action, all such medications seek to reduce tissue edema, facilitate drainage, and maintain the patency of the sinuses.

Unfortunately, the fact that these and other medications are readily available sometimes results in their illicit use. People looking to get high have been known to overdose on pseudoephedrine (a decongestant), dextromethorphan (an antitussive), or diphenhydramine (an antihistamine).

Serious respiratory emergencies often arise from severe narrowing of any portion of the respiratory tract. The respiratory tract is lined by smooth muscle fibers that influence the diameter of the airway. Control of the smooth muscles is maintained by the ANS.

Many respiratory emergency treatments attempt to expand the respiratory tract by using sympathomimetic medications. Complications arise when patients with respiratory emergencies eventually experience decreased amounts of oxygen to the vital organs, including the heart. Increased heart rate and greater force of contraction result in a higher demand for oxygen—but oxygen is already in short supply in a respiratory emergency. Therefore, stimulation of the beta-2 receptors, which produces bronchodilation and vasodilation, is the most beneficial to patients with respiratory emergencies. These drugs produce smaller increases in heart rate and force of contraction, which in turn decreases the amount of oxygen needed for the myocardium to function.

A second-line treatment in a respiratory emergency is from **xanthines**. This class of drugs relieves airway constriction by relaxing the smooth muscles of the bronchioles and stimulating cardiac muscles to work harder, thereby increasing blood flow. These drugs also stimulate the CNS—one notable xanthine is caffeine, the well-known CNS stimulant.

Other respiratory medications suppress the inflammatory response that typically causes acute distress for patients with restrictive airway diseases.

In the acute care setting, corticosteroids, including methylprednisolone (Solu-Medrol) and dexamethasone (Decadron), can be administered for this purpose.

Drugs Affecting the Pancreas

Various hypoglycemic medications are available to affect the pancreas. Still others may not act on the pancreas directly, but instead alter the way insulin (produced by the pancreas) is used by the body. In the absence of pancreatic function, patients may take insulin injections.

To directly affect the pancreas, sulfonylureas increase insulin secretion from the pancreatic beta cells. This medication is effective only if patients have residual beta cell function. Insulin sensitivity is increased by thiazolidinediones and biguanides, which are oral hypoglycemic agents.

Drugs Affecting the Immunologic System

Patients who undergo organ transplantation or have an autoimmune disease are often prescribed **immunosuppressant medications**. Immunosuppressants are intended to inhibit the body's ability to attack the foreign organ, or, in the case of autoimmune diseases, the medications inhibit the body's attack on itself. These drugs are generally derived from fungi or bacteria and tend to have a complicated mechanism of action. Put succinctly, they inhibit lymphocytes and T cells from carrying out their immune functions.

Vitamins and Minerals

Vitamins and minerals are necessary substances that allow for normal metabolism, growth and development, and cellular function. Patients may be taking vitamin and mineral supplements to replace deficient items or as a preventive measure. Vitamins affect a wide variety of functions, but one vitamin used in the prehospital setting is thiamine (vitamin B₁). Thiamine aids in converting carbohydrates into energy. People with alcoholism, among others, tend to be deficient in this vitamin.

Fluids and Electrolytes

Several types of IV fluids may be administered to patients. Crystalloid solutions are typically used in the

prehospital setting and can be isotonic, hypotonic, or hypertonic. Isotonic solutions provide a stable medium for the administration of medication and provide effective fluid and electrolyte replacement. Hypertonic solutions help provide nutrition. Hypotonic solutions are beneficial in dehydration situations but not in hypovolemic cases. In addition to crystalloids, you may administer colloid solutions to your patients. IV fluids are discussed in detail in Chapter 13, *Vascular Access and Medication Administration*.

Street Smarts

When you are questioning a patient about medications, be sure to mention the pertinence of any herbal or OTC preparations. Patients may use herbal alternatives as a substitute for more expensive prescription medications. Most patients do not consider these agents to be “medications” because they do not require a prescription. Any of these may interact with prescribed pharmaceuticals and may produce allergic or idiosyncratic reactions. There are generally no FDA requirements for the manufacture and distribution of herbal preparations. With no regulation, they may be incorrectly prepared or labeled, resulting in serious complications.

Drug Forms

The form that a medication comes in usually determines its route of administration. For example, a tablet or a spray cannot be administered through a needle. The manufacturer chooses the form to ensure the proper route for the medication, the timing of its release into the bloodstream, and its effects on the target organs or body systems. As an AEMT, you should be familiar with the following seven medication forms.

Solid Drugs

Most medications that are given by mouth to adult patients are in tablet or capsule form (**FIGURE 12-7**). Capsules are gelatin shells filled with powdered or liquid medication. If the capsule contains liquid, the shell is sealed and usually soft. If the capsule contains powder, the shell can usually be pulled apart. Tablets often contain other materials that are

FIGURE 12-7 Tablets and capsules are typically taken by mouth and enter the bloodstream through the digestive system.

© Jones & Bartlett Learning.

mixed with the medication and compressed under high pressure.

Some tablets are designed to dissolve very quickly in small amounts of liquid so that they can be given sublingually (SL) and absorbed rapidly. An example is the SL nitroglycerin tablet used for chest pain by patients with cardiac conditions. These medications are especially useful in emergency situations. Tablets may also be ground into a powder, allowing them to be absorbed more quickly. Generally, a medication that must be swallowed is less useful in an emergency because the digestive tract provides a slower route of delivery. For example, an oral pain medication is less useful than an IV pain medication when pain relief is needed within minutes.

Pills are solid drugs that are shaped into a ball or oval to be swallowed. They are often coated to disguise an unpleasant taste.

Suppositories are another form of solid drugs that are administered by inserting them into the rectum. These medications are more rapidly absorbed through the rectal mucosa than those that must travel through the upper portion of the digestive tract. Suppositories are not administered by AEMTs.

Liquid Drugs

A **solution** is a liquid mixture of one or more substances that cannot be separated by filtering or allowing the mixture to stand. Solutions can be given by almost any route. When given by mouth, solutions may be absorbed from the stomach rather

FIGURE 12-8 Nitroglycerin, which is prescribed for chest pain, is often given sublingually as a spray or as a tablet.

© Jones & Bartlett Learning.

quickly because the medication is already dissolved. Solutions that irritate the stomach may be applied topically to the skin, sprayed SL, or inhaled. For example, you may need to assist in the SL delivery of a nitroglycerin spray (**FIGURE 12-8**). Many solutions can be given as an IV, intramuscular (IM), or subcutaneous injection. If a patient has a severe allergic reaction, you may help administer a solution of epinephrine IM using an auto-injector.

Many substances do not dissolve well in liquids. Some of these can be ground into fine particles and evenly distributed throughout a liquid by shaking or stirring. This type of mixture is called a **suspension**. An example of a suspension is activated charcoal, which you may give to patients who have taken overdoses of certain medications or ingested certain poisons.

There are several other types of liquid drugs that you may encounter occasionally that include alcohol in their preparation. Tinctures are liquid preparations that are alcohol based. The name of the material contained in the tincture other than alcohol is added to the name of the tincture, such as tincture of iodine. Spirits are also alcohol solutions that are volatile. Elixirs constitute one of the most common types of medicinal preparations taken orally in liquid form and are made up of a sweetened, aromatic, hydroalcoholic liquid.

Words of Wisdom

Suspensions separate if they stand or are filtered. It is important that you shake a suspension well before administering it to ensure that the patient receives the right amount of medication.

Syrups are mixtures with a high sugar content that are designed to disguise the taste of the medication. These are most commonly used for children's medications. An emulsion is a mixture of two liquids that are not mutually soluble. Emulsions are generally a mixture of water and oil that must be thoroughly shaken to mix.

Metered-Dose Inhalers

If liquids or solids are broken into small enough droplets or particles, they can be inhaled. A **metered-dose inhaler (MDI)** is a miniature spray canister used to direct such substances through the mouth and into the lungs (**FIGURE 12-9**). An MDI delivers the same amount of medication each time it is used. Because an inhaled medication usually is a suspension, the MDI must be shaken vigorously before the medication is administered. Patients with respiratory illnesses such as asthma and emphysema often use MDIs.

Topical Medications

Lotions, creams, and ointments all are **topical medications**, that is, they are applied to the surface of the skin and affect only that area. Of these three, lotions contain the largest amount of water and are absorbed the quickest. Calamine lotion is an example of a medical lotion. Creams, in turn, are absorbed more slowly than lotions but faster than ointments. Hydrocortisone cream, used to diminish skin itching, is an example of a medical cream.

FIGURE 12-9 Some medications are inhaled into the lungs with a metered-dose inhaler so that they can be absorbed into the bloodstream more quickly.

© Jones & Bartlett Learning.

Ointments contain the smallest amount of water, resulting in a slower rate of absorption of the medication. Neosporin first aid ointment is an example of a medical ointment.

Words of Wisdom

Transdermal patches may contain high concentrations of medication that may be released rapidly if the patches are chewed or taken orally through accident or misuse. Children, often toddlers, may face a life-threatening overdose emergency if adult medication patches are chewed. Consult a Poison Control Center or online medical control in these situations. Transdermal patches, such as those containing the potent opioid medication fentanyl (Sublimaze), continually release medication and may complicate resuscitation efforts when left in place on critical patients. Consult local protocols or guidelines regarding the removal of transdermal patches during resuscitation or overdose situations.

Transcutaneous Medications

Transcutaneous or transdermal medications are designed to be absorbed through the skin, or transcutaneously. These medications can affect other areas of the body. Nitroglycerin for patients with chest pain and fentanyl for pain management, for example, are commonly encountered medications that are administered transdermally through a paste or a patch (**FIGURE 12-10**). Nitroglycerin paste usually has properties or delivery systems that help to dilate the blood vessels in the skin, thus speeding absorption into the bloodstream. In contrast to most topical medicines, which work directly on the application site, transcutaneous medications are usually intended for systemic effects.

Safety

If a medication that can be absorbed transdermally comes in contact with your skin while administering it, you can absorb it just as readily as the patient can. When you are removing a medication patch from a patient's skin, be sure not to touch the medication even with your gloves on. Grasp the edge of the dressing or patch with your fingers and gently pull it away from the skin. Use a 4 × 4-inch gauze to wipe the excess medication off the patient.

FIGURE 12-10 Some medications are transcutaneous, or administered through the skin, such as the medication patch shown.

Gels

A **gel** is a semiliquid substance that is administered orally through capsules or plastic tubes. Gels usually have the consistency of pastes or creams but are transparent. Depending on your local protocol, as an AEMT you may give **oral glucose** in gel form to a responsive patient with a low blood glucose level (**FIGURE 12-11**).

FIGURE 12-11 Oral glucose, used in diabetic emergencies, is available in gel and tablet form.

YOU are the Provider

Part 4

Approximately 2 minutes after administration of the naloxone, the patient begins to stir. You inform your partner to stop assisting ventilations and place the patient on a nonrebreathing mask at 15 L/min. He is groggy at first, but quickly regains a more normal mental status, asking what happened. You explain to the patient that you believe that he overdosed on narcotics, to which he states, "Not again." You inform the patient that the medication that you gave him to reverse his overdose might not last as long as the substances are in his system and that he should be transported to the emergency department. He reluctantly agrees to transport. You assist the patient onto the stretcher and initiate nonemergent transport to the hospital. During this time, you are monitoring his airway and mental status to ensure that the naloxone continues to work. On arrival at the emergency department, you turn over care to the awaiting staff.

Recording Time: 16 Minutes

Respirations	16 breaths/min
Pulse	Strong and regular, 68 beats/min
Skin	Warm and dry
Blood pressure	122/74 mm Hg
Oxygen saturation (SpO₂)	100% on 15 L/min via nonrebreathing mask
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

6. What is the half-life of naloxone?

Gases

Gaseous medications are neither solid nor liquid and often are delivered in an operating room. The medication that is most commonly used in gas form in the prehospital setting is oxygen. You might not think of oxygen as a medication because it is all around us and we all use it. However, in its concentrated form, it is a potent medication that has systemic effects. You will usually administer oxygen through a nasal cannula, a nonrebreathing mask, or bag-mask device when ventilating a patient.

Nitrous oxide is another medication that comes in gaseous form and has been used in the prehospital environment. It is an analgesic that may be administered by AEMTs to reduce pain. Nitrous oxide is administered simply by inhalation through a mask and has both analgesic and euphoric effects.

Routes of Drug Administration

The route of drug administration affects the rate at which the onset of action occurs and may affect the therapeutic response that results. The choice of the route of administration is crucial in determining the suitability of a drug. Drugs are given for their local or systemic effects. Absorption is the process by which medications travel through body tissues until they reach the bloodstream.

Enteral drugs are those that are administered along any portion of the gastrointestinal tract. They include the following:

- **Oral.** Many medications are taken by mouth, per os (PO), and enter the bloodstream through the digestive system. This process can take as long as 1 hour.
- **Rectal.** Per rectum (PR) means “by rectum.” There are no AEMT medications that are administered rectally, with the possible exception of 50% dextrose (D₅₀) if allowed by local protocols, and if allowed, rectal administration of D₅₀ would be done only as a last resort.

Parenteral drugs are those that are administered through any route other than the gastrointestinal tract. There are many parenteral routes. Ones with which the AEMT may need to be familiar include the following:

- **Intravenous (IV).** Intravenous means “into the vein.” Medications that need to enter the

bloodstream immediately may be injected directly into a vein. This is the fastest way to deliver a medication, but the IV route cannot be used for all medications. For example, aspirin, oxygen, and charcoal cannot be given by the IV route.

- **Intraosseous (IO).** Intraosseous means “into the bone.” Medications that are delivered via this route reach the bloodstream through the bone marrow. To administer medication into the marrow requires drilling a needle through the bone cortex. Because this is painful, the IO route of delivery is used most often in patients who are unresponsive as a result of cardiac arrest or extreme shock. Most commonly, the IO route is reserved for children who have fewer available (or difficult to access) IV sites.
- **Subcutaneous.** Subcutaneous means “beneath the skin.” A subcutaneous injection is given into the tissue between the skin and the muscle. Because there is less blood here than in the muscles, medications that are delivered via this route are generally absorbed more slowly, and their effects last longer. A subcutaneous injection is a useful way to deliver medications that cannot be taken by mouth, as long as they do not irritate or damage the tissue. Commonly, a daily insulin shot is given this way to a patient with diabetes. Also, epinephrine can be given by this route. Like the IM route, subcutaneous-administered medications are less effective in patients with decreased peripheral perfusion.
- **Intramuscular (IM).** Intramuscular means “into the muscle.” Usually, medications that are administered via IM injection are absorbed quickly because muscles are highly vascular. Some types of medications, though, are designed for a slower, sustained release from the muscle. Many such medications have the prefix “depo” in their names, meaning that they form a deposit in the muscle after being injected. Not all medications can be administered IM. IM injections can cause damage to muscle tissue and result in uneven, unreliable absorption. This is especially true in people who are experiencing decreased peripheral perfusion (as in shock).
- **Sublingual (SL).** Sublingual means “under the tongue.” Medications that take the

SL route, such as nitroglycerin tablets, are absorbed by the venous plexus under the tongue and enter the bloodstream through the oral mucous membranes within minutes. This route not only is faster, it also protects medications from chemicals in the digestive system such as acids that can weaken or inactivate them.

- **Buccal.** The buccal route is similar to the SL route. The medication is placed between the cheek and gums, where it is absorbed into the bloodstream. This is a common route for glucose gel.
- Transcutaneous or transdermal. Both these terms refer to the route of absorbing medication through the layers of the skin and into the bloodstream. Some medications can be absorbed transcutaneously, such as the nicotine in nicotine patches used by people who are trying to quit smoking. On occasion, a medication that comes in another form is administered transcutaneously to achieve a slower, longer-lasting effect. An example is an adhesive patch containing nitroglycerin.
- **Intranasal (IN).** Intranasal is a relatively new format for the delivery of medication. In this route, a medication is pushed through a specialized atomizer device called a **mucosal atomizer device (MAD)**. The liquid medication is turned into a spray and is administered into a nostril. Blood flow to the head and face is very high; therefore, absorption is rather quick with this route. Naloxone can be administered via this route to some patients who are experiencing an overdose.
- **Inhalation.** Drugs administered by the inhalation route are aerosolized and drawn into the lungs through the mouth or nose as the patient breathes. These include nebulized medications and MDIs. Some medications are inhaled into the lungs so that they can be absorbed into the blood more quickly. Others are inhaled because they work in the lungs. Generally, inhalation helps to minimize the effects of the medication in other body tissues. Inhaled medications come in the form of aerosols, fine powders, and sprays.

TABLE 12-7 lists common routes of medication administration and rates of absorption.

TABLE 12-7 Routes of Administration and Rates of Absorption

Route	Rate
Enteral	
Sublingual (SL)	Rapid
Per rectum (PR)	Rapid
Ingestion (oral)	Slow
Parenteral	
Intravenous (IV)	Immediate
Intraosseous (IO)	Immediate
Inhalation	Rapid
Intranasal (IN)	Rapid
Intramuscular (IM)	Moderate
Subcutaneous	Slow
Transcutaneous	Slow

Pharmacokinetics: Movement of Drugs Through the Body

The effectiveness of a drug relates to its pharmaceutical properties, pharmacokinetics, and pharmacodynamics. Pharmaceutical properties determine a drug's concentration at its site of action.

Drugs modify the existing functions of tissues and organs; they do not give new functions to tissues or organs. Also, drugs generally cause multiple actions rather than a single effect. A drug action, as previously discussed, is the result of a physiochemical interaction between the drug and a molecule in the body, such as a receptor.

Once administered, drugs go through four stages: absorption, distribution, metabolism, and excretion. The study of these four stages and the actions of drugs is **pharmacokinetics**.

Principles of Pharmacokinetics

You must carefully consider the pharmacokinetic properties of any medication you are thinking of administering to a patient. As a medication is administered, the body begins a complex process of moving the medication, possibly altering the structure of the

medication, and ultimately removing the medication from the body. The medication dose, route of administration, and clinical status of a patient will largely determine the duration and effectiveness of the medication (called pharmacodynamics, and discussed later in this chapter). The actions of absorption, distribution, biotransformation, and elimination are discussed in detail in the following text.

The pharmacokinetics section of medication profiles typically states the **onset of action**, **peak**, and duration of action for most medications. These values vary by route of administration and may have a broad range, depending on characteristics of individual patients. The onset and peak of a medication are generally related to absorption and distribution. A minimum dose or concentration of medication must be present at certain sites in the body for clinical effects to occur.

The duration of action is generally related to medication metabolism and elimination. As the amount of a medication near cell receptors (or other site of action) decreases, the clinical effects caused by the medication begin to decrease and normal function resumes.

If a medication permanently binds with a receptor site or irreversibly alters the function of a cell, the duration of the medication is determined by the body's ability to regenerate cells. In these cases, the duration of action of a medication may be almost entirely unrelated to the dose or concentration present in the body. A single dose of aspirin, for example, is rapidly eliminated by the body, usually within several hours, but can cause an inhibition of platelet activity lasting for 3 to 10 days.

Drug Absorption

The passage of a substance through some surface of the body into body fluids and tissues is known as absorption. Numerous variables affect drug absorption, including the nature of the absorbing surface, blood flow to the site of administration, solubility of the drug, pH, drug concentration, dosage form, route of administration, bioavailability, diffusion, osmosis, and filtration. **TABLE 12-8** describes these primary factors.

Drug Distribution

Drugs pass freely and quickly out of the vascular space and into the interstitial fluid. Therefore,

blood flow to the area determines the amount of a drug reaching a specific part of the body. Most drugs tend to pass somewhat easily from the intravascular compartment, through the interstitial spaces, and on to their target tissue. These drugs tend to have a rapid onset and a short duration of action. Other drugs become bound to serum proteins in the blood and are not immediately available to act on receptor sites. With the drug bound to the protein, it cannot produce an effect in a receptor site or diffuse through the tissues.

Some areas of the body, such as the brain and placenta, are less accessible to certain drugs than others. Drugs that are protein-bound or in an ionized form are weak penetrators of the blood-brain barrier. The blood-brain barrier and the placental barrier are both less permeable to provide protection to the brain and fetus, respectively.

Biotransformation

Many drugs are inactive when administered and only become active once they have been absorbed and converted into an active form in the blood or by the target tissue. The chemical alteration that a substance undergoes in the body is known as **biotransformation**. The primary organ for biotransformation is the liver. If the liver is diseased, inactivation (detoxification) of drugs may be impaired. This will also increase elimination time of the drug from the body, possibly resulting in toxic blood levels. The liver performs synthetic reactions that yield inactive products (metabolites) that can be secreted by the kidneys, and nonsynthetic reactions, which may result in products that are more active, charged in activity, or less active. The drugs that are biotransformed to an inactive metabolite very quickly have limited effects on the body and must be administered frequently to continue the effect. Epinephrine (administered by paramedics) during a cardiac arrest is an example of a drug that is rendered inactive very quickly and must be administered every 3 to 5 minutes as needed or alternatively as a continuous infusion.

Drug Elimination

Excretion is the elimination of waste products from the body. Drugs are eliminated in their original forms or as metabolites. Organs of excretion include the kidneys via the urine, the intestines through the

TABLE 12-8 Primary Factors of Drug Absorption

Factor	Discussion
Nature of the absorbing surface	Some surfaces are highly permeable. It is much easier for a drug to travel through a single layer of cells than through multiple layers. The greater the surface area exposed to the substance, the greater the absorption.
Blood flow to the site of administration	Blood flow to a particular area regulates how fast the medication is absorbed into the central circulation. This is why administering medications intramuscularly to a patient having a seizure produces a minimal effect. Because of the seizure activity, blood flow to the extremities is diminished. Medications introduced intramuscularly tend to stay in the tissues until the seizure activity stops. When blood flow resumes, the patient may experience the effects of an overdose if multiple doses were given.
Solubility of the drug	The more soluble (dissolvable) the drug, the faster it enters the circulatory system.
pH	The pH of the body and that of the drug can affect the rate of absorption. Some medications are coated to keep them from being absorbed before they reach the small intestine because the acid environment of the stomach can destroy the drug.
Drug concentration	The more of a drug available for absorption, the more that will be absorbed and the more that will remain in the system. Often, a loading dose (bolus) of a medication is given, followed by a continuous infusion to maintain a constant therapeutic level.
Dosage form	Form has a lot to do with the speed of absorption. A liquid will be absorbed much more quickly than a pill, which must be dissolved before it is absorbed.
Routes of administration	IV administration is the most rapid route for delivering drugs in the prehospital environment. The medication bypasses the gastrointestinal absorption process because it is introduced directly into the vascular system. Intramuscular and subcutaneous routes are much slower because they depend on blood flow to the area in which the medication is administered.
Bioavailability	Bioavailability is the rate and extent to which an active drug enters the general circulation, permitting access to the site of action. It is determined by measurement of the concentration of the drug in body fluids.
Diffusion	Diffusion is the movement of solutes (molecules) from an area of higher concentration to an area of lower concentration.
Osmosis	Osmosis is the movement of a solvent (fluid) from an area of lower solute concentration to an area of higher solute concentration.
Filtration	Filtration is the removal of particles from a solution by allowing the liquid portion to pass through a membrane or other partial barrier. The semipermeability of the membrane allows fluid to pass through, but the openings are too small for solid particles.

Abbreviations: IV, intravenous; pH, potential of hydrogen

© Jones & Bartlett Learning.

feces, the lungs via respiration, the sweat glands through perspiration, and the mammary glands through breast milk. The rate of elimination varies with the amount of drug in the body and the underlying condition of the excretion organs. During shock, when the kidneys are poorly perfused, drugs may remain in the circulation for longer periods.

This also holds true for geriatric patients whose kidneys may not function as well owing to the normal deterioration associated with aging and for patients with chronic kidney disease. A patient's poor ability to eliminate a drug may result in an accumulation of the drug if subsequent doses are given, resulting in toxic effects.

Special Populations

Geriatric patients often take many medications. They might also save medications left over from previous medical conditions to use if they need them in the future. Make every effort to identify which medications are current and what conditions they are being used to treat. Ask family members to help distinguish current from outdated medications, or look at the expiration dates on the medication labels. Take a list of the current medications or the drugs themselves with you to the emergency department.

Elderly patients can become confused about their medication regimen. Uncertainty about whether they missed a dose may cause them to repeat the medication, possibly resulting in an overdose. If you think an overdose has occurred, contact medical control.

Along with the potential for overdosing, the physiologic effects of aging can result in altered pharmacodynamics and pharmacokinetics. As the body ages and organs (such as the liver and kidneys) function less effectively, medications are not processed and filtered out of the system as quickly as in a younger person. Each time a dose of a drug is taken, it results in overaccumulation of that drug in the body. Decreased gastric motility can result in greater absorption time, and a decrease in total body water along with an increase in fat can result in a greater concentration of drugs with weight-based dosages.

Medications can interact with each other, creating potentially harmful conditions for the patient. Even though a medication may be indicated for a certain condition, it might be contraindicated in the presence of another medication. For example, if the patient is taking the heart medication propranolol (Inderal), which is a beta-blocker, and has an acute episode of shortness of breath, any asthma remedy might be rendered ineffective. Bronchodilation is a beta effect of most emergency asthma medications.

Medications such as sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra)—all of which are used to treat erectile dysfunction—can have potentially fatal interactions with common heart medications, specifically nitroglycerin. If used in combination with any of these medications, nitroglycerin can cause life-threatening hypotension due to severe vasodilation. Ask a patient who has been prescribed nitroglycerin if he has used Viagra in the past 24 hours, or Cialis or Levitra within the past 48 hours. Report this to medical control.

Although medications help people to recover from acute conditions and adjust to chronic diseases, they can pose serious problems for geriatric patients. You should distinguish current from previous medications, suspect accidental or intentional overdoses, and be prepared for potentially lethal medication interactions. Document all findings, and inform medical control.

Pharmacodynamics

Pharmacodynamics is the way in which a medication produces the response we intended, also known as the mechanism of action. A medication's pharmacodynamics also include factors that may alter the intended response and any side effects or unexpected effects.

Mechanism of Action

To produce optimal desired or therapeutic effects, a drug must reach appropriate concentrations at its site of action. Molecules of the chemical compound must proceed from the point of entry into the body to the tissues with which they react. The magnitude of the response depends on the dose and the time that it takes the drug to travel in the body.

Drugs may produce their effects locally, systemically, or both. Local effects are those that result

from the direct application of a drug to a tissue. An example of a local effect would be when cortisone cream is applied to the skin to relieve itching. Systemic effects occur after the drug is absorbed by any route and distributed by the bloodstream. Systemic effects almost always involve more than one organ, although the response of one or another organ may predominate.

Medications cause their action on the body by the following four mechanisms:

- They may bind to a receptor site.
- They may change the physical properties of cells—typically, by changing the osmotic balance.
- They may chemically combine with other chemicals (such as with the goal of turning the substance into a nonproblematic chemical).
- They may alter a normal metabolic pathway (such as by interrupting the normal growth process of cells).

Medications that bind to a receptor site are the most prevalent, particularly in the prehospital setting. Cellular responses can be wide ranging depending on the chemical mediator and the cells being stimulated. The medication molecule must compete with the naturally occurring chemical mediator. To win this battle, the medication molecule must have a higher affinity for the receptor than the naturally occurring chemical mediator does, or it must be present in a higher concentration. In addition, more than one medication may vie for the same receptor.

After the medication binds to the receptor site, it initiates a chemical change that produces the expected effect. In some cases, this chemical change *is* the intended effect. In other cases, the initial chemical change releases a second compound (known as a second messenger) that causes the intended effect.

Drug-Response Relationship

After the medication finds the target tissue, it needs to accumulate to a sufficient concentration to produce its desired effect. The drug-response relationship correlates the amount of medication given and the response it causes.

When administering a medication, you need to know the onset of action and duration of action. The **termination of action** is the amount of time after the concentration level falls below the minimum level to the time it is eliminated from the body. All of these factors affect the **therapeutic index**—the ratio of a drug’s lethal dose for 50% of the population (LD_{50}) to its effective dose for 50% of the population (ED_{50}). In other words, the therapeutic index gives an indication of a medication’s margin of safety. Each medication also has a biologic half-life—that is, the time it takes the body to eliminate one-half of the drug. For example, the half-life of naloxone is typically 45 minutes.

The minimum concentration required to produce the desired response is referred to as the **therapeutic threshold** or the minimum effective concentration. A concentration lower than the therapeutic threshold will not induce the desired clinical response. A concentration higher than the therapeutic threshold may actually be detrimental and possibly fatal. The goal of drug therapy is to give the minimum concentration of a drug that will produce the desired effects.

TABLE 12-9 lists factors that alter drug responses.

TABLE 12-9 Factors Altering Drug Responses	
Factor	Description
Age	As the body ages, metabolism slows and the organs of excretion do not always function as well as those in younger patients. This can cause a toxic level of drugs in the system if not considered when administering multiple doses. Likewise, infants and small children have immature organs and systems and cannot metabolize the same amount of drug as an adult.
Body mass	Many medications are given based on the patient’s weight. This is especially true of children. To have a therapeutic dose, concentrations within the tissues must meet the desired level.
Sex	Owing to different body compositions of fat, water, and hormones, certain medications affect males and females differently and must be adjusted accordingly.
Environmental conditions and time of administration	Factors such as time of day, temperature, altitude, and even noise may alter the body’s response to a drug.
Genetic factors	Patients who may already have some compromise in function as a result of an existing condition may not be adversely affected by certain medications because of changes in absorption, distribution, metabolism, and excretion.
Psychological factors	Mental stresses can have negative effects on the entire system, resulting in an inability to properly metabolize medications.

Factors Influencing Medication Interactions

Many variables influence **medication interactions**. When you are administering medications, it is important to know not only how they affect the patient, but also how they may affect other medications that were previously administered. An interaction between medications occurs whenever the actions of one drug on the body are in some way modified by another chemical substance. This chemical substance may be another prescription, herbal, or OTC medication; something like nicotine from cigarette smoking; something in the patient's diet; or anything to which the person is exposed. One example is the use of bronchodilators that may be exacerbated by ingesting caffeine. The caffeine stimulates the CNS and may produce adverse effects.

It is important to be aware of the potential interactions of medications that are prescribed and those that the patient may be self-administering. Many patients, especially elderly patients, may take several medications each day (**polypharmacy**). The chance of developing an undesired medication interaction increases rapidly with the number of medications used. This also is true when patients take medications that may interact with other substances such as particular foods and alcohol. Warning labels on prescription bottles warn against the substances that may cause interactions. Unfortunately, however, many people do not read the warning labels.

Predictable Responses

Because of the extensive research that goes into developing and testing a medication before it is approved, there is common knowledge about what effect a specific medication will have on the patient. Obviously, an AEMT expects to see the desired response after administering the medication. At the same time, you should anticipate responses beyond the desired effect. *Side effects* are any actions of a medication other than the desired ones. Side effects may occur even when a medication is administered properly and under the appropriate circumstances. For example, giving epinephrine to a patient who is having an allergic reaction should dilate the bronchioles and decrease wheezing. However, two side effects of epinephrine are cardiac stimulation and

constriction of the arteries, which may elevate the patient's heart rate and blood pressure. These side effects are predictable.

Iatrogenic Responses

An **iatrogenic response** is an adverse condition inadvertently induced in a patient by the treatment given. One example is a urinary tract infection that develops in a patient after insertion of an indwelling catheter (such as a Foley catheter). When the administration of medications results in symptoms that mimic naturally occurring disease states, it is known as an iatrogenic medication response.

Unpredictable Responses

Some patients may have adverse effects that are not anticipated. The most common unpredictable response encountered in the prehospital setting is an allergic reaction. An allergy develops when a person has previously been exposed to a specific antigen and develops antibodies against that substance (sensitization). After a person has become sensitized, subsequent exposure to that same substance results in **hypersensitivity**. Because the patient is hypersensitive, the medication activates the immune system. Allergic reactions are unpredictable—unless the patient has had an allergic reaction to the same medication in the past—and may result in life-threatening anaphylaxis. Anaphylaxis is an acute systemic reaction that is usually life threatening. An allergic reaction may be immediate or delayed. Before administering any medication, if possible, question the patient carefully about any known medication allergies. The AEMT should remain alert for an allergic reaction after administering *any* medication.

A delayed reaction is known as **serum sickness**. This type of reaction is a hypersensitivity similar to an allergy and occurs a considerable time after a stimulus, such as a skin inflammation occurring hours or days after exposure to the allergen. Unlike other allergic reactions to medications that occur soon after administration, serum sickness can develop 7 to 14 days after the first exposure to a medication.

In rare cases, the patient may experience a completely unique response that is specific to that person; it is not seen in other patients. This situation is known as an **idiosyncrasy**. An **idiosyncratic reaction**

is a peculiar or individual reaction to a drug. For example, if a patient were administered nitroglycerin and then experienced a seizure, this would be an idiosyncratic reaction because seizure is not an expected reaction when administering nitroglycerin.

Patients who take a specific medication for an extended period can build up **tolerance** to it. In these cases, the patient will have a decreased response to the same amount of medication, often requiring higher doses than normal. Also, a patient can develop a tolerance to other drugs in a certain class as a result of prolonged administration of another medication in that same class. Known as **cross-tolerance**, this phenomenon is often seen in patients who take many pain medications. When patients are taking a medication such as oxycodone, they become tolerant to opiate-based medications. If morphine is administered for pain, the patient may not have the same response as other patients because of cross-tolerance. A disease or condition that does not respond to treatment is known as **refractory**.

Any medication needs to reach a minimum concentration in the target tissue before it becomes effective; that concentration is reached by providing a specific dose. If several doses are given in a relatively short time, the patient may experience a cumulative effect. A **cumulative effect** is the increased effect when a medication is given in several successive doses, which might result in therapeutic or nontherapeutic effects.

With prolonged administration of a medication, a patient can become drug dependent. *Drug dependence* is a psychological and sometimes physical state resulting from continued use of a substance. Characteristic behavioral response includes a compulsion to take the drug on a continuous or periodic basis to experience its effects or to avoid the discomfort of its absence. People will have significant symptoms if they stop using the medication. **Habituation** is the term for physical tolerance of and psychological dependence on a drug or drugs.

Many patients take multiple medications at one time. It is possible for the effects of one medication to alter the response of another medication, a phenomenon known as a drug interaction. A drug interaction can be fatal. The interaction may not always be anticipated. Even if two medications are sympathomimetics, for example, it does not necessarily mean the patient will experience a more

dramatic sympathetic response. It is possible to see the opposite response or a completely unrelated response. When a patient is taking multiple medications, one medication could block the body's response to another medication (**drug antagonism**). You can use this fact as an advantage. For example, if the patient has taken an opiate-based drug such as morphine, you have the ability to administer another medication, naloxone, to block the response to the morphine.

A **summation effect** is an additive effect—that is, two drugs that have the same or similar effect increase the patient's response when both are administered to the patient. When the patient receives two drugs that have the same effect but produce a response greater than the sum of their individual responses, the result is known as **synergism**. At times, the interaction between two medications can cause one drug to enhance the effect of another, known as **potentiation**. For example, acetaminophen (Tylenol) and alcohol interact. In this case, it is well known that high doses of acetaminophen are damaging to the liver. When alcohol is ingested along with acetaminophen, more of the medication is taken up into the liver and may result in acute liver failure. Some potentiation effects are known and can be exploited to achieve a desired effect; in other cases, potentiation may occur unexpectedly. A direct biochemical interaction that takes place between two drugs is referred to as **interference**.

Reducing Medication Errors

As an AEMT, you will have the difficult task of assessing patients, performing invasive procedures, and administering medications in the uncontrolled prehospital setting. In this environment, patient history is often limited, inaccurate, or nonexistent. AEMTs do not always have the time or resources for a careful evaluation of the risks and benefits associated with medications that they are considering administering to a patient. Medication decisions are often based on memory and frequently occur in the context of a stressful, life-threatening patient situation. AEMTs are constantly at risk for a cognitive error such as choosing the wrong medication or dose, or a technical error such as administering more volume of medication than was intended. **TABLE 12-10** lists the rights of medication administration.

TABLE 12-10 The Rights of Medication Administration**Right Patient**

Although you will typically treat one patient at a time, sometimes you may have to treat multiple patients. It is essential to confirm the identity of a patient before administering any medication—especially when patients are unresponsive or are unable to communicate (because of extremes of age, altered consciousness, or other factors). Always attempt to have patients confirm their identity verbally, or confirm the identity of the patient yourself through identification devices (such as bracelets or identification cards), to the extent possible. A critical issue, as identified in the SAMPLE history, is to ensure that the patient does not have allergies to the medication or medications you intend to give (**FIGURE 12-12**).

Right Medication and Indication

Administration of the wrong medication is the most common pharmacology-related error. Several factors may lead to “wrong medication” errors, including similar packaging and labeling, similar names and storage practices, and ineffective communication. Always repeat (echo) the medication order out loud and in the presence of your partner, and confirm that the packaging matches the intended order. While checking the packaging, confirm that the medication is not expired by reading the expiration date out loud to your partner. Avoid using abbreviations, and always recheck the order before administration. Confirm indications and contraindications. Ensure that the medication is appropriate for the patient’s medical condition and medical history.

Right Dose

Doses of nearly every medication depend on patient-specific factors (such as condition, weight, and age). The actual dose needed is often not equal to the amount supplied in an ampule or a prefilled syringe in the prehospital setting. Therefore, you will have to calculate the patient-specific dose. When calculating the correct dose, always recheck your math, and if possible, have your partner recheck and verify the final dose.

Right Route

Many medications can be administered by a variety of routes; the optimal route depends on the patient’s condition and the speed with which the medication needs to take effect. Errors can occur when medication doses and routes are confused. For example, IV drip doses can be different from doses for the same medication injected into an IV as a bolus. Another important route-related issue is the patient’s condition. If a patient is in profound shock, you must consider how well the medication will be absorbed and distributed to target tissues. Choosing the right route helps enable the medication to have the correct effect. Always verify the route of administration.

Right Time

Because all medications take a certain amount of time to take effect and may have the potential to interfere with other medications, you must always follow the recommended guidelines for the proper frequency of medication administration. Evaluate the patient’s condition before and after you administer any medication, and document any noted response or change in the patient’s condition. Also remember that some medications require a specific administration frequency to maintain a therapeutic level.

Right Patient Education

Patient education should begin as soon as possible. Responsive patients should be informed of any pertinent risks and benefits prior to medication administration. Involve responsive patients in ongoing evaluation and monitoring by informing them of any important symptoms they may experience or that should be reported.

Right to Refuse

Respect patient autonomy. Patients with decision-making capacity or a surrogate decision maker may refuse medications and other interventions, even if refusing a medication may result in harm. Consult online medical control in any high-risk situation. Make sure the patient is aware of the potential consequences of refusing a medication or treatment.

Right Response and Evaluation

Continually monitor your patient. Observe for desired effects and any possible adverse reactions for any medication administered. Certain medications may require careful monitoring; other medications may require multiple doses to achieve the desired effect.

Right Documentation

Because AEMTs frequently transfer care of a patient to other health care providers, it is critical to document in writing the medications administered, the dose, when they were administered, and the effects the patient experienced. Whenever possible, communicate this information in writing (on the patient care report), and in a verbal report to the next level of care.

Abbreviations: AEMT, advanced emergency medical technician; IV, intravenous; SAMPLE, Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury

© Jones & Bartlett Learning.

FIGURE 12-12 Angioedema is acute swelling, sometimes of the lips and tongue, that may be caused by an allergic reaction. Some medications cause angioedema after the first or second dose.

© E. M. Singletary, MD. Used with permission.

Use a current, reliable medication reference source whenever administering potentially unfamiliar medications or whenever an unusual dose or route of administration is being considered. Technical errors can be avoided by having a partner confirm the volume in a syringe or a weight-based medication calculation. Many health care settings require that two providers check pediatric and high-risk medication calculations. AEMTs should also evaluate for a patient medication allergy or hypersensitivity before each medication administration.

The Institute for Safe Medication Practices has developed a list of medication abbreviations prone to causing errors. When these symbols and abbreviations are used by physicians, AEMTs, and other health care providers, there is an increased likelihood of a medication error as a result of miscommunication. The full list is exhaustive. **TABLE 12-11**

TABLE 12-11 Examples of Errors and Misinterpretations in Reporting

Error Source	Intended Meaning	Possible Misinterpretation	Correction
Trailing zero after the decimal point (eg, 4.0 mg)	4 mg	40 mg	Avoid trailing zeros when decimal place is not needed.
No leading zero before decimal point (eg,.8 mg)	0.8 mg	8 mg	Use a zero before the decimal point when the dose is less than 1 unit.
SC	Subcutaneous	SL (sublingual)	Write out “subcutaneous.”
IN	Intranasal	IV (intravenous) or IM (intramuscular)	Write out “intranasal.”

© Jones & Bartlett Learning.

Words of Wisdom

Wichita-Sedgwick County EMS System in Kansas developed a tool known as Medication Administration Cross-Check (MACC) (FIGURE 12-13).⁶ This tool uses principles of crew resource management by requiring a process for verification for every medication, every time. The tool employs job aids to help reduce cognitive load and ensure the process is completed each time a medication is administered.

Because EMS systems vary in configuration—for example, an AEMT working with an EMT—the tool is designed to work with all provider levels. Although BLS providers may lack familiarity with all medications, they can verify quantities, medication names, expiration dates, etc.

More important, the second provider, regardless of certification level, acts as a sounding board for the first provider. This forces the first provider to validate the medication administration. Some providers may catch the error as they read it back to themselves. Others may catch it when the second provider asks them to repeat something that did not sound right. Sometimes the second provider can catch the error and bring it to the first provider's attention. The tool will not eliminate all medication errors. However, with proper use of this tool, medication errors can be significantly reduced.

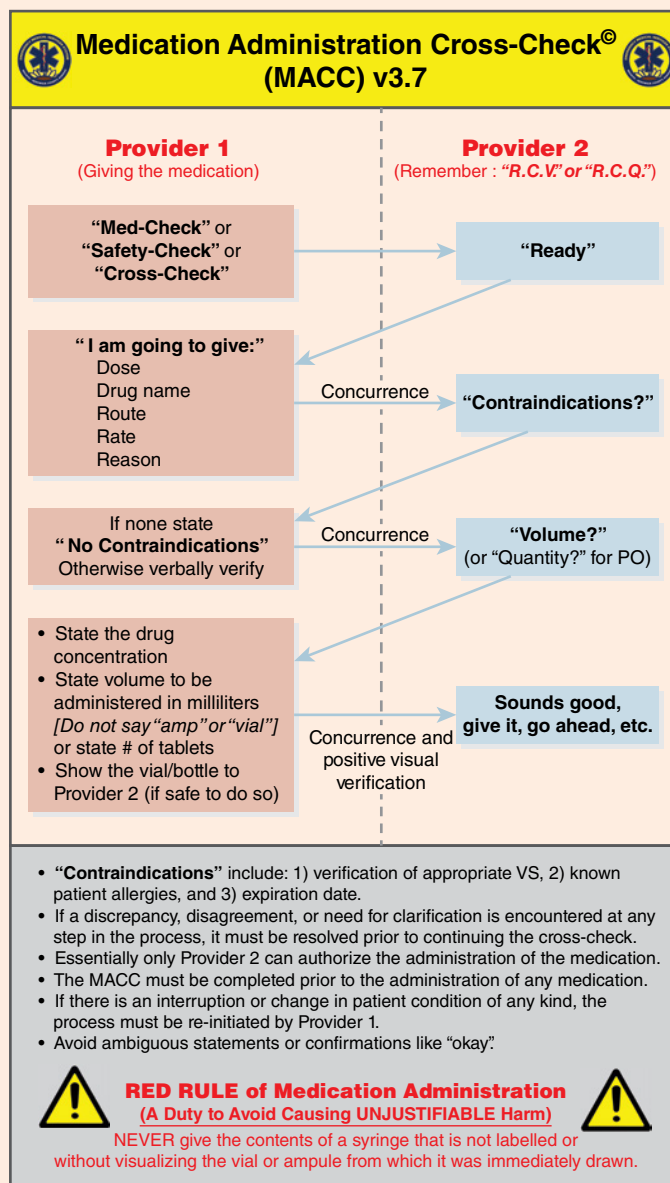

FIGURE 12-13 Medication Administration Cross-Check® job aid.

Reproduced from: Misasi P, Braithwaite S. The Medication Administration Cross-Check® (MACC) User's Manual. Wichita-Sedgwick County EMS System. March 2012.

lists several important sources of error relevant to the prehospital setting.

Specific Medications

A certified AEMT is allowed to administer or help patients self-administer numerous medications. Details about each of these are provided in

Documentation & Communication

Documenting medication administration is extremely important. You must list the dose administered, name of the medication, route, rate, time of administration, who administered the drug, who helped perform the medication check, and the patient's response.

Words of Wisdom

“Tall man” lettering is sometimes used to avoid confusion of medications with similar spellings.⁷ With tall man lettering, capitalized letters highlight the area that differentiates the medication from others with similar names. Use of tall man lettering is intended to help reduce medication-related errors. Consider how tall man lettering helps differentiate the following names:

- hydr**ALAZINE**, hydr**OXY**zine
- Oxy**CONTIN**, Oxy**CODONE**, **HYDRO**codone

- Epinephrine (IM or subcutaneous)
- MDI medications—albuterol
- Nebulized medications—albuterol
- Nitroglycerin—spray, tablets, paste
- Nitrous oxide
- Naloxone
- Aspirin
- Others based on local protocols

However, you may administer or help to administer these medications only under the following conditions:

- A licensed physician gives you a direct order to administer a medication, and/or the local medical protocols under which you are working permit you to administer that medication. Some local protocols exclude one or more of the medications listed in Table 12-12.
- The local medical protocols under which you are working include standing orders for the use of a medication in defined situations. It is imperative that you do not give or help patients take any other medications under any circumstances.

TABLE 12-12. As an AEMT, you may administer the following:

- Oxygen
- Oral glucose
- Glucagon
- IV dextrose (eg, D₅₀, D₂₅, or D₁₀)
- IV fluids—D₅W (5% dextrose in water), normal saline, lactated Ringer solution

TABLE 12-12 Medications, Fluids, and Routes Used at the AEMT Level^a

Albuterol (Proventil, Ventolin)	
Class	Sympathomimetic, bronchodilator
Mechanism of action	Selective beta-2 agonist that stimulates adrenergic receptors of the sympathetic nervous system. Causes smooth muscle relaxation in the bronchial tree and peripheral vasculature.
Indications	Treatment of bronchospasm in patients with reversible obstructive airway disease (COPD/asthma). Prevention of exercise-induced bronchospasm.
Contraindications	Known prior hypersensitivity reactions to albuterol. Tachycardia dysrhythmias, especially those caused by digitalis. Synergistic with other sympathomimetics.
Adverse reactions/side effects	Often dose-related and include headache, fatigue, light-headedness, irritability, restlessness, aggressive behavior, pulmonary edema, hoarseness, nasal congestion, increased sputum, hypertension, tachycardia, dysrhythmias, chest pain, palpitations, nausea/vomiting, dry mouth, epigastric pain, and tremors.
Drug interactions	Tricyclic antidepressants may potentiate vasculature effects. Beta-blockers are antagonistic and may block pulmonary effects. May potentiate hypokalemia caused by diuretics.
Route	Inhalation (nebulizer or MDI)

(continues)

TABLE 12-12 Medications, Fluids, and Routes Used at the AEMT Level^a (*continued*)

Dosage and administration	<i>Adult:</i> Administer 2.5 mg. Dilute in 0.5 mL of 0.5% solution for inhalation with 2.5 mL normal saline in nebulizer and administer over 10–15 minutes. MDI: 1–2 inhalations (90–180 mcg); wait 5 minutes between inhalations. <i>Pediatric:</i> <20 kg: 1.25 mg/dose via handheld nebulizer or mask over 20 minutes; >20 kg: 2.5 mg/dose via handheld nebulizer or mask over 20 minutes. Repeat once in 20 minutes.
Duration of action	<i>Onset:</i> 5–15 minutes. <i>Peak effect:</i> 30 minutes to 2 hours. <i>Duration:</i> 3–4 hours.
Special considerations	Pregnancy safety: Emergency use of albuterol in pregnancy is generally considered safer than withholding the medication. May precipitate angina pectoris and dysrhythmias. In prehospital emergency care, albuterol should be administered only via inhalation. Patients may need to be coached on proper use of MDI, particularly with spacer.
Aspirin (Acetylsalicylic Acid)	
Class	Platelet inhibitor, anti-inflammatory agent
Mechanism of action	Prevents the formation of thromboxane A ₂ , which causes platelets to clump together (aggregate) and form plugs that cause obstruction or constriction; has antipyretic and analgesic properties.
Indications	New-onset chest discomfort that suggests ACS.
Contraindications	Hypersensitivity. Relatively contraindicated in patients with active ulcer disease or asthma.
Adverse reactions/side effects	Bronchospasm, anaphylaxis, wheezing in allergic patients, prolonged bleeding, GI bleeding, epigastric distress, nausea/vomiting, heartburn, Reye syndrome.
Drug interactions	Use with caution in patients allergic to NSAIDs.
Route	Oral (chewable tablet[s])
Dosage and administration	<i>Adult:</i> 160 to 325 mg PO. Chewing is preferred to swallowing. <i>Pediatric:</i> Not recommended.
Duration of action	<i>Onset:</i> 5–30 minutes. <i>Peak effect:</i> 1–3 hours. <i>Duration:</i> 3–6 hours.
Special considerations	Pregnancy safety: Use cautiously during pregnancy, weighing risks and benefits. If there are no contraindications, non-enteric-coated, chewable aspirin should be given as soon as possible to all patients with a suspected ACS as soon as possible after symptom onset. Not recommended in pediatric population.
Dextrose	
Class	Carbohydrate, antihypoglycemic, hypertonic solution
Mechanism of action	Rapidly increases serum glucose levels. Short-term osmotic diuresis.
Indications	Hypoglycemia, altered level of consciousness, coma of unknown origin, seizure of unknown origin, status epilepticus.
Contraindications	Intracranial hemorrhage with normal blood glucose level.
Adverse reactions/side effects	Extravasation leads to tissue necrosis. Cerebral hemorrhage; cerebral ischemia; pulmonary edema; warmth, pain, burning from IV infusion; hyperglycemia.
Drug interactions	Sodium bicarbonate, warfarin (Coumadin)

Route	IV, IO
Dosage and administration	<i>Adult:</i> D₅₀ 25 g slow IV push. May be repeated as necessary. 10% dextrose (D₁₀) may be an option. D₁₀ can be as effective as D₅₀ and D₂₅, with fewer potential side effects. Consult your local protocols regarding the concentrations used in your system. <i>Pediatric:</i> 1 year and older; dextrose 25% 0.5–1 g/kg/dose slow IV push. May be repeated as necessary. As with adults, in pediatric patients other concentrations of dextrose, such as D₁₀, may be used depending on local protocol. <i>Neonates and infants:</i> D₁₀ 200–500 mg/kg slow IV push (see below). May be repeated as necessary. Maximum concentration of 12.5% (vasculature extremely sensitive to high concentrations).
Duration of action	<i>Onset:</i> Less than 1 minute. <i>Peak effect:</i> Variable. <i>Duration:</i> Variable.
Special considerations	Pregnancy safety: Draw blood to determine glucose level before administering. Do not administer to patients with known CVA unless hypoglycemia documented. Due to potential medication shortages, this may not be available in bolus form.
Epinephrine (Adrenalin) 1 mg/mL (1:1,000)	
Class	Sympathomimetic
Mechanism of action	Direct-acting alpha and beta agonist. Alpha: vasoconstriction. Beta-1: positive inotropic, chronotropic, and dromotropic effects. Beta-2: bronchial smooth muscle relaxation and dilation of skeletal vasculature. Blocks histamine receptors.
Indications	Allergic reaction, anaphylaxis, asthma
Contraindications	None in the emergency setting. Relative contraindications include hypertension, hypothermia, pulmonary edema, myocardial ischemia, hypovolemic shock.
Adverse reactions/side effects	Nervousness, restlessness, headache, tremor, pulmonary edema, dysrhythmias, chest pain, hypertension, tachycardia, nausea/vomiting.
Drug interactions	Potentiates other sympathomimetics; MAOIs may potentiate effect. Beta-blockers may blunt effect.
Route	IM, subcutaneous
Dosage and administration	<i>Adult:</i> Allergic reactions and asthma: 0.3–0.5 mg (0.3–0.5 mL of 1 mg/mL [1:1,000]) IM. <i>Pediatric:</i> Anaphylaxis/severe status asthmaticus: 0.01 mg/kg (0.01 mL/kg) IM of a 1 mg/mL (1:1,000) solution (maximum single dose: 0.3 mg).
Duration of action	<i>Onset:</i> Immediate. <i>Peak effect:</i> Minutes. <i>Duration:</i> Several minutes.
Special considerations	Pregnancy safety: If administered for anaphylaxis, risk of withholding outweighs risk to both mother and fetus of administration. May cause syncope in children with asthma. May increase myocardial oxygen demand.
Glucagon (GlucaGen)	
Class	Hyperglycemic agent, pancreatic hormone, insulin antagonist
Mechanism of action	Increases blood glucose level by stimulating glycogenolysis. Unknown mechanism of stabilizing cardiac rhythm in beta-blocker overdose. Minimal positive inotropic and chronotropic response. Decreases GI motility and secretions.
Indications	Altered level of consciousness when hypoglycemia is suspected. May be used as a reversal agent in beta-blocker overdose.

(continues)

TABLE 12-12 Medications, Fluids, and Routes Used at the AEMT Level^a (*continued*)

Contraindications	Hyperglycemia, hypersensitivity.
Adverse reactions/side effects	Dizziness, headache, hypertension, tachycardia, nausea/vomiting, rebound hypoglycemia.
Drug interactions	Incompatible in solution with most other substances. No significant drug interactions with other emergency medications.
Route	IM, IN
Dosage and administration	<i>Adult:</i> Hypoglycemia: 1 mg IM/IN; may repeat in 7–10 minutes. <i>Pediatric:</i> Hypoglycemia: 1 mg IM/IN if 20 kg or greater (or 5 years or more); 0.5 mg IM/IN if less than 20 kg or younger than 5 years.
Duration of action	<i>Onset:</i> 1 minute. <i>Peak effect:</i> 5–20 minutes. <i>Duration:</i> 60–90 minutes.
Special considerations	Pregnancy safety: Use in pregnancy only if clearly indicated. Not recommended for use in lactating women. Ineffective if glycogen stores depleted. Should always be used in conjunction with D ₅₀ whenever possible. If patient does not respond to a second dose of glucagon, D ₅₀ must be administered. Requires reconstitution with the supplied solution.
Naloxone Hydrochloride (Narcan)	
Class	Opioid antagonist, antidote
Mechanism of action	Competitive inhibition at narcotic receptor sites. Reverses respiratory depression secondary to opiate drugs. Completely inhibits the effect of morphine.
Indications	Opiate overdose, complete or partial reversal of CNS and respiratory depression induced by opioids, decreased level of consciousness, coma of unknown origin. Narcotic agonist for the following: morphine sulfate, heroin, hydromorphone (Dilaudid), methadone, meperidine (Demerol), paregoric, fentaNYL (Sublimaze), oxycodone (Percodan), codeine, propoxyphene (Darvon). Narcotic agonist and antagonist for the following: butorphanol (Stadol), pentazocine (Talwin), nalbuphine (Nubain).
Contraindications	Use with caution in narcotic-dependent patients. Use with caution in neonates of narcotic-addicted mothers.
Adverse reactions/side effects	Restlessness, seizures, dyspnea, pulmonary edema, tachycardia, hypertension, dysrhythmias, nausea/vomiting, withdrawal symptoms in opioid-addicted patients, diaphoresis.
Drug interactions	Incompatible with bisulfite and alkaline solutions.
Route	IV, IN, IO, IM (auto-injector)
Dosage and administration	<i>Adult:</i> 0.4–2.0 mg IM/IV/IO; minimum single dose recommended, 2 mg. Repeat at 5-minute intervals to a maximum total dose of 10 mg (medical control may request higher amounts). For IN route, administer one-half of the dose in each nostril; maximum dose is 1 mL per nostril. <i>Pediatric:</i> 0.1 mg/kg per dose IV/IO/IM every 2 minutes as needed. Maximum total dose of 2 mg. If no response in 10 minutes, administer an additional 0.1 mg/kg per dose.
Duration of action	<i>Onset:</i> Less than 2 minutes. <i>Peak effect:</i> Variable. <i>Duration:</i> 30–60 minutes.

Special considerations	Pregnancy safety: Use in pregnancy if clearly indicated. Use in breastfeeding women should be clearly indicated. Assist ventilations prior to administration to avoid sympathetic stimulation. Seizures without causal relationship have been reported. May not reverse hypotension. Use caution when administering to narcotic addicts (potential violent behavior). Half-life of naloxone is often shorter than the half-life of narcotics; repeat dosing may be required. In cardiac arrest, naloxone is generally not beneficial.
Nitroglycerin (Nitrostat, Nitro-Bid, Tridil)	
Class	Vasodilator
Mechanism of action	Smooth muscle relaxant acting on vasculature, bronchial, uterine, intestinal smooth muscle. Dilation of arterioles and veins in the periphery. Reduces preload and afterload, decreasing workload of the heart and thereby myocardial oxygen demand.
Indications	Acute angina pectoris, ischemic chest pain, hypertension, heart failure, pulmonary edema.
Contraindications	Hypotension, hypovolemia, intracranial bleeding or head injury, pericardial tamponade, severe bradycardia or tachycardia, previous administration in the last 24 hours: sildenafil (Viagra) or 48 hours: vardenafil (Levitra) or tadalafil (Cialis).
Adverse reactions/side effects	Headache, dizziness, weakness, reflex tachycardia, syncope, hypotension, nausea/vomiting, dry mouth, diaphoresis, muscle twitching.
Drug interactions	Additive effects with other vasodilators. Incompatible with other IV drugs.
Route	SL (rapid absorption), IV
Dosage and administration	<i>Adult:</i> 0.4 mg SL; may repeat in 3–5 minutes to maximum of 3 doses. Nitroglycerin spray: 0.4 mg under the tongue; 1–2 sprays. Nitroglycerin IV infusion: begin at 10 to 20 mcg/min; increase by 5–10 mcg/min every 5 minutes until desired effect. <i>Pediatric:</i> Not recommended.
Duration of action	<i>Onset:</i> 1–3 minutes. <i>Peak effect:</i> 5–10 minutes. <i>Duration:</i> SL: 20–30 minutes; IV: 1–10 minutes after discontinuation of infusion.
Special considerations	Pregnancy safety: Has been used safely during pregnancy. Use caution with breastfeeding women and monitor infants for adverse effects. Hypotension more common in older patients. Nitroglycerin decomposes when exposed to light or heat; must be kept in airtight containers. Active ingredient may have a stinging effect when administered.
Nitropaste (Nitro-Bid Ointment)	
Class	Vasodilator
Mechanism of action	Smooth muscle relaxant acting on vasculature, bronchial, uterine, intestinal smooth muscle. Dilation of arterioles and veins in the periphery. Reduces preload and afterload, decreasing workload of the heart and thereby myocardial oxygen demand.
Indications	Angina pectoris, chest pain associated with AMI, hypertension, heart failure, pulmonary edema.
Contraindications	Hypotension, hypovolemia, intracranial bleeding or head injury, previous administration in the last 24 hours of sildenafil (Viagra) or in the last 48 hours of vardenafil (Levitra) or tadalafil (Cialis).

(continues)

TABLE 12-12 Medications, Fluids, and Routes Used at the AEMT Level^{1a} (*continued*)

Adverse reactions/side effects	Headache, dizziness, weakness, reflex tachycardia, syncope, hypotension, nausea, vomiting, dry mouth, muscle twitching, diaphoresis.
Drug interactions	Additive effects with other vasodilators.
Route	Transdermal
Dosage and administration	<i>Adult:</i> Paste: Apply 1/2- to 3/4-inch (1- to 2-cm) line (15–30 mg), cover with wrap, and secure with tape. Maximum: 5-inch (12.5-cm) line (75 mg) per application. Transdermal: Apply unit to intact skin (usually chest wall) in varying doses. <i>Pediatric:</i> Not recommended.
Duration of action	<i>Onset:</i> 30 minutes. <i>Peak effect:</i> variable. <i>Duration:</i> 18–24 hours.
Special considerations	Pregnancy safety: Has been used safely during pregnancy. Use caution with breastfeeding women and monitor infants for adverse effects. Not a great value in prehospital arena. Wear gloves when applying paste. Store paste in cool place with tube tightly capped. Erratic absorption rates quite common.
Nitrous Oxide 50:50 (Nitronox)	
Class	Gaseous analgesic and anesthetic
Mechanism of action	Exact mechanism unknown; affects CNS phospholipids.
Indications	Moderate to severe pain, anxiety, apprehension
Contraindications	Impaired level of consciousness, head injury, inability to follow or comply with instructions, decompression sickness (nitrogen narcosis, air embolism, air transport), undiagnosed abdominal pain or marked distention, bowel obstruction, hypotension, shock, COPD, cyanosis, chest trauma with pneumothorax.
Adverse reactions/side effects	Light-headedness, drowsiness, respiratory depression, apnea, nausea/vomiting, malignant hyperthermia.
Drug interactions	None of significance.
Route	Inhalation
Dosage and administration	<i>Adult:</i> Instruct the patient to inhale deeply through demand valve and mask or mouthpiece. <i>Pediatric:</i> Same as adult.
Duration of action	<i>Onset:</i> 2–5 minutes. <i>Peak effect:</i> Variable. <i>Duration:</i> 2–5 minutes.
Special considerations	Pregnancy safety: Nitrous oxide increases the incidence of spontaneous abortion and should therefore be avoided in pregnant women if alternatives are available. Ventilate patient care area during use. Nitrous oxide is nonflammable and nonexplosive. Nitrous oxide is ineffective in 20% of the population.
Oral Glucose (Insta-Glucose)	
Class	Hyperglycemic, carbohydrate
Mechanism of action	After absorption in the GI tract, glucose is distributed to the tissues providing an increase in circulating blood glucose levels.
Indications	Alert patients with suspected hypoglycemia.
Contraindications	Decreased level of consciousness, nausea, vomiting.

Adverse reactions/side effects	Nausea, vomiting.
Drug interactions	None
Route	Oral, buccal
Dosage and administration	<i>Adult:</i> 25 g PO in patients with intact gag reflex and ability to manage their own secretions. Pastes or gels should be placed between the cheek and gum for absorption. <i>Pediatric:</i> 0.5–1 g PO in patients with intact gag reflex and ability to manage their own secretions.
Duration of action	<i>Onset:</i> 10 minutes. <i>Peak effect:</i> Variable. <i>Duration:</i> Variable.
Special considerations	Must be swallowed. Glucose is not absorbed sublingually or buccally. Check a glucometer reading before administering oral glucose and repeat at least 10 minutes after.
Oxygen	
Class	Naturally occurring atmospheric gas
Mechanism of action	Reverses hypoxemia.
Indications	Confirmed or expected hypoxemia, ischemic chest pain, respiratory insufficiency, prophylactically during air transport, confirmed or suspected carbon monoxide poisoning, all other causes of decreased tissue oxygenation, decreased level of consciousness.
Contraindications	Certain patients with COPD or emphysema who will not tolerate oxygen concentrations greater than 35%, hyperventilation.
Adverse reactions/side effects	Decreased level of consciousness (COPD patients), decreased respiratory drive in COPD patients, dry mucous membranes.
Drug interactions	None
Route	Inhalation
Dosage and administration	<i>Adult:</i> Cardiac arrest and carbon monoxide poisoning: 100%. Hypoxemia: 10–15 L/min via nonrebreathing mask. COPD: 0–2 L/min via nasal cannula or 28%–35% Venturi mask. Be prepared to provide ventilatory support if higher concentrations of oxygen needed. <i>Pediatric:</i> Same as for adult with exception of premature infant.
Duration of action	<i>Onset:</i> Immediate. <i>Peak effect:</i> Not applicable. <i>Duration:</i> Less than 2 minutes.
Special considerations	Be familiar with liter flow rates and each type of delivery device used. Supports combustion.
IV Solutions	
Lactated Ringer (Hartmann) Solution	
Class	Isotonic crystalloid solution
Mechanism of action	Lactated Ringer solution replaces water and electrolytes.
Indications	Hypovolemic shock; keep open IV line, hypoperfusion.
Contraindications	Lactated Ringer solution should not be used in patients with heart failure or renal failure.

(continues)

TABLE 12-12 Medications, Fluids, and Routes Used at the AEMT Level^{1a} (*continued*)

Adverse reactions/side effects	Rare in therapeutic dosages.
Drug interactions	Few in the emergency setting.
Route	IV
Dosage and administration	Hypovolemic shock; titrate according to patient's physiologic response.
Duration of action	Short-term therapy.
Special considerations	None
5% Dextrose in Water	
Class	Hypotonic dextrose-containing solution
Mechanism of action	D ₅ W provides nutrients in the form of dextrose as well as free water.
Indications	IV access for emergency medications; for dilution of concentrated medications for IV infusion.
Contraindications	D ₅ W should not be used as a fluid replacement for hypovolemic states.
Adverse reactions/side effects	Rare in therapeutic dosages.
Drug interactions	D ₅ W should not be used with phenytoin (Dilantin) or amrinone (Inocor).
Route	IV
Dosage and administration	D ₅ W is usually administered through a minidrip (60 drops/mL) set at a rate of "to keep open."
Duration of action	Short-term therapy.
Special considerations	None
0.9% Sodium Chloride (Normal Saline)	
Class	Isotonic crystalloid solution
Mechanism of action	Normal saline replaces water and electrolytes.
Indications	Heat-related problems (heat exhaustion, heatstroke), freshwater drowning, hypovolemia, diabetic ketoacidosis, keep open IV.
Contraindications	The use of 0.9% sodium chloride should not be considered in patients with heart failure because circulatory overload can be easily induced.
Adverse reactions/side effects	Rare in therapeutic dosages.
Drug interactions	Few in the emergency setting.
Route	IV
Dosage and administration	The specific situation being treated will dictate the rate at which normal saline will be administered. In severe heatstroke, diabetic ketoacidosis, and freshwater drowning, it is likely that you will be called on to administer the fluid quite rapidly. In other cases, it is advisable to administer the fluid at a moderate rate (for example, 100 mL/h). Neonates: Fluid bolus: 10-mL/kg IV given over 5–10 minutes; multiple boluses may be administered if the patient remains clinically hypovolemic. In a neonate, a 10-mL/kg normal saline bolus may aid in improved perfusion and clearance of acid.

Duration of action	Short-term therapy.
Special considerations	None

^a Local protocols vary and may not include all of these medications, or may include some of the above routes but not others, and medication concentrations may vary. Always follow local protocols regarding medications to administer, forms, routes, and dosages.

Abbreviations: ACS, acute coronary syndrome; AMI, acute myocardial infarction; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; D₅W, 5% dextrose in water; D₅₀, 50% dextrose in water; GI, gastrointestinal; IM, intramuscular; IN, intranasal; IO, intraosseous; IV, intravenous; MAOIs, monoamine oxidase inhibitors; MDI, metered-dose inhaler; NS, normal saline; NSAID, nonsteroidal anti-inflammatory drug; PO, per os (orally); SL, sublingual

YOU are the Provider SUMMARY

1. Are there any potential hazards with this scene?

As with any call that you respond to, scene safety is paramount. This patient has a known history of IV drug abuse; therefore, contaminated uncapped needles may be present. Also, when the patient becomes alert, he may become hostile and combative.

2. What medication might the AEMT carry that would be appropriate to administer in this situation?

An AEMT may be approved by the medical director to carry and administer the medication naloxone (Narcan), which is given to patients with an acute narcotic overdose.

3. By which route or routes may naloxone be administered?

Naloxone may be administered IV, IM, subcutaneously, intranasally, and IO. Each route of administration has its own risks and benefits and should be carefully evaluated to ensure that you are administering the medication by the best route for that patient.

The standard adult dose of naloxone is 0.4 to 2 mg by slow IV push. Naloxone administration may be repeated at 5-minute intervals if needed. If no response is seen after a total of 10 mg has been administered, you need to consider another cause of the patient's unresponsiveness.

Precautions to naloxone administration include using caution when administering to patients with supraventricular dysrhythmias, head injuries, and increased intracranial pressure. Naloxone may also cause seizures, so you should use caution in administering the drug to patients with convulsive disorders. Because the duration of action of naloxone is shorter than that of narcotics, repeated doses of naloxone may be necessary when treating a patient who is not an addict but has overdosed on narcotics.

4. What class of medication is naloxone?

Naloxone is classified as an opioid antagonist. An opioid antagonist competitively binds with the opiate receptors. As a result of this binding, the opioid molecules cannot get to the receptor.

5. What is the mechanism of action of naloxone?

Naloxone works by competitively inhibiting at narcotic receptor sites. This competitive action displaces narcotic analgesics from their receptor sites, blocking their effects, which include CNS depression and respiratory depression.

6. What is the half-life of naloxone?

Naloxone generally begins acting within 2 minutes, and its effects typically last for 30 to 60 minutes.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 4-20-20	Incident No.: 20183724	Nature of Call: Unresponsive		Location: Main & Central	
Dispatched: 0112	En Route: 0116	At Scene: 0120	Transport: 0131	At Hospital: 0140	In Service: 0200

Patient Information**Age:** 39**Sex:** M**Weight (in kg [lb]):** 55 kg (122 lb)**Allergies:** None**Medications:** None**Past Medical History:** IV drug abuser per PD**Chief Complaint:** Unresponsive**Vital Signs**

Defibrillation	Bleeding Control	Bandaging	Splinting	Other: 0.4 mg naloxone IN

Narrative

EMS dispatched to above location for unresponsive male. On arrival find Denville Police Department officer with patient. Patient is unresponsive and apneic. Police officer assisting ventilations with pocket mask. Officer states patient is well known to him, known history of IV heroin use. Ventilations assisted with bag-mask device. Rapid assessment reveals fresh track marks found on arms, no obvious trauma. Pupils constricted and sluggish. 0.4 mg naloxone given intranasally (left naris). After approximately 2 minutes, patient begins to arouse, but groggy. Ventilations stopped, patient placed on nonbreathing mask at 15 L/min. Informed patient that he overdosed on narcotics, to which he replied, "Not again." Advised of need to be evaluated at ED, to which patient reluctantly agreed. Assisted patient to stretcher, secured, transported nonemergent. En route: Patient maintains patent airway, AO×4, calm and cooperative throughout transport. On arrival at ED, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- Pharmacology is the study of the properties (characteristics) and effects of drugs and medications on the body. Drugs are substances that produce a physiologic effect, whether therapeutic or not. Medications are chemical agents used to treat or prevent disease or relieve pain. They have intended effects, unintended effects, and may have untoward effects (those that can be harmful to the patient).
 - There are indications and contraindications for each medication. Indications are the therapeutic uses for a particular medication. Contraindications are cases in which you should not give a patient medication.
 - As an AEMT you must be familiar with the various names of medications (trade, generic, chemical, official), the sources of medications, their classification, and sources where information on medications may be obtained.
 - The manufacture of pharmaceuticals in most countries is regulated to protect consumers. For example, standardized manufacturing is required for uniform strength and purity.
 - The Controlled Substances Act of 1970 is comprehensive legislation dealing with narcotic and nonnarcotic drugs that have a potential for abuse and consists of five categories or schedules according to abuse potential. Schedule I represents the highest abuse potential and Schedule V is the lowest.
 - Medications must go through an approval process that includes animal studies and clinical trials in humans before being approved for distribution.
 - There are special considerations for certain groups of patients when administering medications: geriatric, pediatric, and pregnant patients. With pregnant patients, the health of the mother is the priority in emergency situations.
- The US Food and Drug Administration uses a detailed system that includes narrative summaries regarding specific pregnancy, lactation, and reproductive risks.
- There are several medication concerns related to geriatric patients. Effects of a medication may be delayed. Geriatric patients often take several medications, making drug interaction possible. Alterations in mental status can result in overdosing or underdosing.
 - As an AEMT, you are held responsible for safe and therapeutically effective medication administration. This includes legal, moral, and ethical considerations.
 - Drugs are grouped into classifications based on their effect on a body system, or their mechanism of action (how they create the effect).
 - To understand the effects drugs have on the body, you must have an understanding of the nervous system. The sympathetic nervous system is responsible for the body's response to shock and stress ("fight or flight"). The parasympathetic nervous system relaxes the body, controlling automatic functions during non-stressful times ("rest and digest").
 - Adrenergic receptors cause a response in the target organ and are grouped as alpha-1, alpha-2, beta-1, and beta-2. Some medications stimulate alpha and beta receptors, whereas others may block specific receptors.
 - Drugs that produce the same effects as sympathetic nervous system hormones are sympathomimetics. Drugs that have the opposite effect are sympatholytics.
 - Agonists aid or increase effects. Antagonists antagonize or fight the effects of another substance.
 - Beta-blockers are used to control blood pressure in some patients and heart rhythm

disturbances in others. Beta-blockers work by filling a portion of the beta receptor sites to prevent binding by beta stimulators that occur naturally in the body and can be introduced as a medication.

- Agonists to the parasympathetic nervous system are known as parasympathomimetics, and antagonists are known as parasympatholytics. One of the most commonly used parasympatholytics is the drug atropine that is used for symptomatic bradycardia and exposure to organophosphates and certain chemical nerve agents.
- Analgesics include medications that relieve pain. The most common class of medications used for analgesia in the prehospital setting comprises the opioid agonists. Opioid antagonists reverse the effects of opioid drugs. Opioid agonist-antagonists have agonistic and antagonistic properties. They are often preferred because they can decrease pain but do not diminish the function of the respiratory system or result in dependence or addiction.
- Sedative-hypnotics do what their name suggests: sedate and produce hypnosis. They are preferred for invasive procedures. Drugs that create sedation and hypnosis include benzodiazepines, barbiturates, opioid agonists, nonbarbiturate hypnotics, and dissociative anesthetic agents.
- Stimulants excite the central nervous system, whereas depressants slow brain activity.
- Drugs that affect the cardiac system may affect heart rate, force of contraction, or velocity of conduction through the heart. Cardiac glycosides, antidysrhythmics, and antihypertensive medications are included in this group.
- Antihypertensive medications include diuretics, vasodilator medications, angiotensin-converting enzyme inhibitors, and calcium channel blockers.
- Certain medications prevent or minimize the effects of thrombi. These include antiplatelet agents, anticoagulants, and fibrinolytics.
- Drugs that affect the respiratory system include oxygen, OTC decongestants, bronchodilators, and xanthines.
- Drugs come in many different forms, including solid, liquid, inhaled, topical, transcutaneous, gels, and gases. Liquid intravenous (IV) medications are some of the most common medications in the prehospital setting.
- You should also know the various routes of medication administration and which routes are used for the drugs you may administer in the prehospital setting. Routes include enteral and parenteral.
- Enteral drugs are those that are administered along any portion of the gastrointestinal tract, including the oral and rectal routes.
- Parenteral drugs are those that are administered through any route other than the gastrointestinal tract and include IV, intraosseous (IO), subcutaneous, intramuscular (IM), sublingual (SL), buccal, transcutaneous, intranasal, and inhalation.
- After drugs are administered, they go through four stages: absorption, distribution, metabolism, and excretion.
- Pharmacokinetics is the study of the metabolism and action of drugs with emphasis on the time required for absorption, duration of action, distribution in the body, and method of excretion. The onset of action, peak, and duration of action are important concepts in pharmacokinetics.
- Pharmacodynamics is the way in which a medication produces the response we intended, also known as the mechanism of action. It also encompasses the factors that may alter the intended response and any side effects or unexpected effects.
- Factors that alter drug response include age, body mass, sex, environmental conditions, time of administration, genetic factors, and psychological factors.
- Responses beyond the desired effect are side effects and may occur even when a medication is administered properly.

- Unpredictable responses may occur when a medication is administered. These include allergic reaction, serum sickness, and idiosyncratic reaction. Other effects that may occur include cumulative effect, summation, potentiation, drug dependence, and drug interaction.
- Administering medication includes the risk of making an error. To minimize errors, follow the rights of medication administration. Follow a procedure such as a medication administration cross-check to ensure safe administration.
- Certain medication abbreviations are prone to causing errors. Become familiar with these so you can decrease the chance of misinterpretation.
- Overall, it is important to learn as much as you can about the medications you may be allowed to administer in your area. Carry a pharmacologic reference to look up medications that may be unfamiliar.
- You should also be aware of proper medication storage and security. Follow local protocols for medication administration, and review pharmacology often.

Vital Vocabulary

absorption In pharmacology, the process by which medications travel through body tissues until they reach the bloodstream; in allergic reactions, when foreign material is deposited on and moves into the skin.

action The expected therapeutic effect of a medication on the body.

adrenergic Pertaining to nerves that release the neurotransmitter norepinephrine or noradrenaline; also pertains to the receptors acted on by norepinephrine.

agonist A substance that mimics the actions of a specific neurotransmitter or hormone by binding to the specific receptor of the naturally occurring substance.

analgesics A classification for medications that relieve pain or induce analgesia.

angiotensin-converting enzyme (ACE)

inhibitors Medications that suppress the conversion of angiotensin I to angiotensin II.

antagonist A substance that counteracts the action of something else; a drug of this type has an affinity for a cell receptor and, when it binds to that receptor, the cell is prevented from responding.

anticholinergic Of or pertaining to blockage of acetylcholine receptors, resulting in inhibition of transmission of parasympathetic nerve impulses.

anticoagulant drugs The medications used to prevent intravascular thrombosis by preventing blood coagulation in the vascular system.

anticonvulsant medications The medications used to treat seizures, which are believed to work by inhibiting the influx of sodium into cells.

antidysrhythmic medications The medications used to treat and prevent cardiac rhythm disorders.

antihypertensives The medications used to control blood pressure.

antiplatelet agents The medications that interfere with the collection of platelets.

autonomic nervous system (ANS) The part of the nervous system that regulates functions that are not controlled consciously, but rather involuntarily, such as heart rate, blood pressure, digestion, and sweating.

barbiturates Any medications of a group of barbituric acid derivatives that act as central nervous system depressants and are used as sedatives or hypnotics; potent sedative-hypnotics historically used as sleep aids, as antianxiety drugs, and as part of the regimen for seizure control.

benzodiazepines Sedative-hypnotic drugs that provide muscle relaxation and mild sedation, commonly used to treat anxiety, seizures, and

alcohol withdrawal; includes drugs such as diazepam (Valium) and midazolam (Versed).

beta-blocker A common class of cardiac drugs that blocks beta effects, causing a decrease in the workload of the heart by reducing the speed of contraction, as well as reducing blood pressure.

bioavailability The rate at and extent to which an active drug enters the general circulation, permitting access to the site of action.

biotransformation The chemical alteration that a substance undergoes in the body.

buccal A medication route in which the medication is placed between the cheek and gums, where it is absorbed into the bloodstream.

calcium channel blockers The medications that suppress dysrhythmias, provide more oxygen to the heart via coronary artery dilation, and reduce peripheral vascular resistance.

cardiac glycosides A classification of medications that naturally occur in plant substances and that block certain ionic pumps in the membranes of heart cells, which indirectly increases calcium concentrations; an example is digoxin.

chemical name Precise description of a drug's chemical composition and molecular structure.

cholinergic Fibers in the parasympathetic nervous system that release a chemical called acetylcholine.

chronotropic Affecting the rate of contraction of the heart.

contraindications Situations in which a medication should not be given because it would not help or may actually harm a patient.

cross-tolerance A tolerance to a particular drug that crosses over to other drugs in the same class.

cumulative effect Action of increased intensity after administration of several doses of a drug.

depressants Agents used to slow brain activity.

diffusion The movement of solutes (molecules) from an area of higher solute concentration to an area of lower solute concentration.

dissociative anesthetic agents A category of drugs that cause profound dissociation and general anesthesia, often used as an adjunct to facilitate airway placement in the prehospital environment; includes ketamine.

diuretic medications The medications designed to promote elimination of excess salt and water by the kidneys.

dose The amount of medication given on the basis of the patient's size and age.

dromotropic Affecting the velocity of conduction in the heart.

drug antagonism A decrease in the action of a drug by the administration of another drug.

drug dependence A psychological and sometimes physical state resulting from continued use of a substance, characterized by a compulsion to take the drug on a continuous or periodic basis to experience its effects or to avoid the discomfort of its absence.

drugs Chemical agents used in the diagnosis, treatment, and prevention of disease.

duration of action The amount of time a medication concentration can be expected to remain above the minimum level needed to provide the intended action.

enteral Drugs that are administered along any portion of the gastrointestinal tract, including the oral and rectal routes.

excretion The elimination of waste products from the body.

extrapyramidal symptoms A wide array of symptoms such as involuntary movements, tremors, rigidity, muscle contractions, restlessness, and changes in breathing and heart rate, usually as a result of taking antipsychotic drugs.

fibrinolytic agent Medication that dissolves blood clots after they have already formed; promotes the digestion of fibrin.

filtration A type of diffusion in which water carries dissolved compounds across the cell membrane; commonly used by the kidneys to clean blood.

gel A semiliquid substance that is administered orally through capsules or plastic tubes.

generic name The original chemical name of a medication (in contrast with one of its trade names); not capitalized.

habituation The situation in which there is a physical tolerance and psychological dependence on a drug or drugs.

half-life The time required by the body, tissue, or organ to metabolize or inactivate one-half of the amount of a substance taken in; an important consideration in determining the proper dose of drug and frequency of administration.

hypersensitivity Abnormal sensitivity; a condition in which the body manifests an exaggerated response to the stimulus of a foreign agent.

iatrogenic response An adverse condition induced in a patient by the treatment given.

idiosyncrasy An abnormal sensitivity or reaction to a drug or other substance that is peculiar to an individual.

idiosyncratic reaction A peculiar or individual response to a drug or medication through unusual susceptibility.

immunosuppressant medications The medications intended to inhibit the body's ability to attack the "foreign" transplanted organ or in the case of autoimmune diseases, the medications that inhibit the body's attack on itself.

indications Therapeutic uses for a specific medication.

inhalation The active, muscular part of breathing that draws air into the airway and lungs; a medication delivery route; in allergic reactions, breathing in foreign substances through the respiratory system.

inotropic Affecting the contractility of muscle tissue, especially cardiac muscle.

intended effect The effect that a medication is expected to have on the body.

interference A direct biochemical interaction between two drugs.

intramuscular (IM) Injection into a muscle; a medication delivery route.

intranasal (IN) A delivery route in which a medication is pushed through a specialized atomizer device, called a mucosal atomizer device, into the naris.

intraosseous (IO) Injection into the bone; a medication delivery route.

intravenous (IV) Injection directly into a vein; a medication delivery route.

mechanism of action The way in which a medication produces the intended response.

medication A chemical substance that is used to treat or prevent disease or relieve pain.

medication interactions Situations in which the effects of one medication alter the response of another medication.

metered-dose inhaler (MDI) A miniature spray canister used to direct medications through the mouth to be inhaled into the lungs.

mucosal atomizer device (MAD) A device that attaches to the end of a syringe that is used to spray (atomize) certain medications via the intranasal route.

muscarinic cholinergic antagonists Medications that block acetylcholine exclusively at the muscarinic receptors; an example is atropine.

nonbarbiturate hypnotics Medications designed to sedate without the side effects of a barbiturate.

nonopioid analgesics Medications designed to relieve pain without the side effects of opioids.

nonsteroidal anti-inflammatory drugs (NSAIDs) Medications with analgesic and fever-reducing properties.

official name Drug name assigned by the *United States Pharmacopeia (USP)*, generally the generic name followed by "USP."

onset of action The time needed for the concentration of the medication at the target tissue to reach the minimum effective level.

opioid agonist-antagonists Medications designed to relieve pain without the side effects of opioids.

opioid agonists Chemicals that are similar to or derived from the opium plant.

opioid antagonists A classification of medications that reverse the effects of opioid drugs.

oral By mouth; a medication delivery route.

oral glucose A simple sugar that is readily absorbed by the bloodstream; it is carried on the EMS unit.

osmosis The movement of a solvent (fluid), such as water, from an area of lower solute concentration to one of higher concentration through a selectively permeable membrane to equalize concentrations of a solute on both sides of the membrane.

over-the-counter (OTC) medications Medications that may be purchased directly by a patient without a prescription.

parasympathetic nervous system A subdivision of the autonomic nervous system, involved in control of involuntary, vegetative functions, mediated largely by the vagus nerve through the chemical acetylcholine; the part of the autonomic nervous system that relaxes the body.

parasympatholytics Drugs that block the actions of the parasympathetic nervous system; also known as anticholinergics.

parasympathomimetics Drugs that produce the same effects as those of the parasympathetic nervous system; also known as cholinergics.

parenteral Drug administration through any route other than through the gastrointestinal tract; includes intravenous, intraosseous, subcutaneous, intramuscular, sublingual, buccal, transcutaneous, intranasal, and inhalation.

peak In a pharmacologic context, the point of maximum effect of a drug.

pH The measure of acidity or alkalinity of a solution.

pharmacodynamics The study of drugs and their actions on living organisms.

pharmacokinetics The study of the metabolism and action of drugs with a particular emphasis on the time required for absorption, duration of action, distribution in the body, and method of excretion.

pharmacology The study of the properties and effects of medications.

polypharmacy The simultaneous use of many medications by the same patient.

potassium channel blockers Medications that increase the contractility of the heart and work against the reentry of blocked impulses.

potentiation Enhancement of the action of a drug by the administration of another drug.

prescription medications Medications that are distributed to patients only by pharmacists according to a physician's order.

rectal Through the rectum; a medication delivery route.

refractory Describes a disease or condition that does not respond to treatment.

serum sickness A condition in which antigen-antibody complexes formed in the bloodstream deposit in sites around the body, most notably in the kidney, with resultant inflammatory reactions.

side effects Any effects of a medication other than the desired ones.

sodium channel blockers Antidysrhythmic medications that slow conduction through the heart.

solution A liquid mixture that cannot be separated by filtering or allowing the mixture to stand.

stimulants Medications or chemicals that temporarily enhance central nervous system and sympathetic nervous system functioning and produce an excited state.

subcutaneous Into the tissue between the skin and muscle; a medication delivery route.

sublingual (SL) Administration under the tongue; a medication delivery route.

summation effect Increased effect that may occur when two drugs that have the same or similar action are given together.

suspension A mixture of ground particles that are distributed evenly throughout a liquid but do not dissolve.

sympathetic blocking agents Subdivision of the autonomic nervous system that governs the body's fight-or-flight reactions by inducing smooth muscle contraction or relaxation of the blood vessels and bronchioles; responsible for the body's response to shock and stress.

sympathetic nervous system Part of the autonomic nervous system that is responsible for the body's response to shock and stress.

sympatholytics Drugs that block the actions of the sympathetic nervous system.

sympathomimetics Drugs that produce the same effects as the hormones of the sympathetic nervous system.

synergism The action of two substances such as drugs, in which the total effects are greater than the sum of the independent effects of the two substances.

teratogenic Poses a risk to the normal development or health of the unborn fetus.

termination of action The amount of time after the concentration of a medication falls below

the minimum effective level until it is eliminated from the body.

therapeutic index The difference between the minimum effective concentration and the toxic level of a drug.

therapeutic threshold The minimum concentration of a drug necessary to cause the desired response.

tolerance Physiologic adaptation to the effects of a drug, such that increasingly larger doses of the drug are required to achieve the same effect.

topical medications Lotions, creams, and ointments that are applied to the surface of the skin and affect only that area; a medication delivery route.

toxicity The risk that a substance will pose a health hazard to an individual or organism.

trade name The brand name that a manufacturer gives a medication; capitalized.

transcutaneous Through the skin; a medication delivery route; also called transdermal.

unintended effects Actions that are undesirable but pose little risk to the patient.

untoward effects Actions that can be harmful to the patient.

vasodilator medications The medications that work on the smooth muscles of the arterioles and/or the veins.

xanthines A classification of medications that affect the respiratory smooth muscle and that relax bronchiole smooth muscles, stimulate cardiac muscle, and stimulate the central nervous system.

Chapter 13

Vascular Access and Medication Administration

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Pharmacology

Applies (to patient assessment and management) fundamental knowledge of the medications carried by advanced emergency medical technicians (AEMTs) that may be administered to a patient during an emergency.

Medication Administration

- Routes of administration (pp 705–707, 715–716)
- Self-administer medication (p 750)
- Peer-administer medication (pp 700–728)
- Assist/administer medications to a patient (pp 735–755)

Emergency Medications

- Names (Chapter 12, *Principles of Pharmacology*)
- Effects (Chapter 12, *Principles of Pharmacology*)

- Indications (Chapter 12, *Principles of Pharmacology*)
- Routes of administration (pp 735–755)
- Dosages for the medications administered (pp 733–735 and Chapter 12, *Principles of Pharmacology*)
- Actions (Chapter 12, *Principles of Pharmacology*)
- Contraindications (Chapter 12, *Principles of Pharmacology*)
- Complications (Chapter 12, *Principles of Pharmacology*)
- Side effects (pp 716–720, 728 and Chapter 12, *Principles of Pharmacology*)
- Interactions (Chapter 12, *Principles of Pharmacology*)

KNOWLEDGE OBJECTIVES

1. Describe the role of medical direction in medication administration, and explain the difference between direct orders (online) and standing orders (off-line). (p 690)
2. Explain the rights of medication administration and describe how each one relates to emergency medical services. (pp 690–692)
3. Explain why determining a patient's prescription and over-the-counter (OTC) medications is a critical aspect of patient assessment. (pp 690–691)
4. Discuss basic cell physiology and how it relates to intravenous (IV) therapy. (p 692)
5. List commonly used IV fluid compositions and types of IV solutions. (pp 658–699)
6. Discuss the techniques for performing IV therapy. (pp 700–721)
7. Discuss the factors to consider when choosing an IV solution. (pp 701–702)
8. Discuss the factors to consider when choosing an administration set. (pp 702–705)

9. Discuss the factors to consider when choosing an IV site. (pp 705–707)
10. List types of IV catheters. (pp 707–708)
11. Discuss alternative IV sites and techniques. (pp 715–716)
12. Describe complications that can occur as a result of IV therapy. (pp 716–720)
13. Describe special considerations when performing IV therapy on a pediatric or geriatric patient. (pp 720–721)
14. Discuss the techniques for establishing an intraosseous (IO) line. (pp 721–728)
15. List the types of IO devices available. (pp 723–725)
16. Discuss the possible complications of IO infusion. (p 728)
17. Discuss the systems of weights and measures used when administering medication. (pp 733–734)
18. Explain principles of drug dose calculations, including desired dose, concentration on hand, volume on hand, volume to administer, and IV drip rate. (pp 733–734)
19. Discuss the advantages, disadvantages, and techniques for administering the following routes:
 - Oral administration (pp 735–736)
 - Rectal administration (p 736)
 - Subcutaneous administration (pp 741–742)
 - Intramuscular administration (pp 742–744)
 - Sublingual administration (pp 744–746)
 - Intranasal administration (pp 746–747)
 - Administration by inhalation (pp 747–751)
 - IV administration (pp 751–754)
 - IO administration (p 754)

SKILLS OBJECTIVES

1. Demonstrate the process an AEMT should use when following the rights of medication administration. (pp 690–692)
2. Demonstrate how to spike an IV bag. (pp 704–705, Skill Drill 13-1)
3. Demonstrate how to obtain vascular access. (pp 711–714, Skill Drill 13-2)
4. Demonstrate how to gain IO access. (pp 726–727, Skill Drill 13-3)
5. Demonstrate how to administer oral medication to a patient. (pp 735–736)
6. Demonstrate how to draw medication from an ampule. (p 738, Skill Drill 13-4)
7. Demonstrate how to draw medication from a vial. (pp 738–739, Skill Drill 13-5)
8. Demonstrate how to administer a subcutaneous medication to a patient. (pp 741–742, Skill Drill 13-6)
9. Demonstrate how to administer an intramuscular medication to a patient. (pp 742–744, Skill Drill 13-7)
10. Demonstrate how to administer a sublingual medication to a patient. (pp 744–746, Skill Drill 13-8)
11. Demonstrate how to administer an intranasal medication to a patient. (pp 746–747, Skill Drill 13-9)
12. Demonstrate how to administer a medication via inhalation to a patient. (pp 747–751)
13. Demonstrate how to assist a patient with a metered-dose inhaler (MDI). (p 750, Skill Drill 13-10)
14. Demonstrate how to assist a patient with a small-volume nebulizer. (pp 747–751, 752–753, Skill Drill 13-11)
15. Demonstrate how to administer a medication via the IV bolus route. (p 753, Skill Drill 13-12)
16. Demonstrate how to administer a medication via the IO route. (pp 754–755, Skill Drill 13-13)

Introduction

Before you administer any medication to a patient, you must have a thorough understanding of how the medication will affect the body—both negatively and positively. This includes familiarity with the medication's mechanism of action, indications, contraindications, routes of administration, dose, adverse reactions, and what to do in the event of an adverse reaction. This also is true of medications belonging to the patient that you may assist the patient in taking. See Chapter 12, *Principles of Pharmacology*, for more information on medication properties.

The first rule of medicine is “First, do no harm.” For example, administering the medication glucagon to a patient who is not hypoglycemic could result in hyperglycemia and potential compromise and cause harm to the patient. It is therefore paramount to ensure that a specific medication is clearly indicated to treat the patient's condition. A careful assessment of the patient will help ensure that only beneficial medications are administered (**FIGURE 13-1**).

Intravenous (IV) therapy is one of the most invasive procedures an advanced emergency medical technician (AEMT) learns. During your career in emergency medical services (EMS), few procedures will require more training or practice. Proficiency in IV therapy and technique is required for most advanced life support procedures.

A medical problem of any type alters a person's established balance among the systems (internal environment) of the body. This balance, called **homeostasis**, produces optimal physical performance. It is the job of health care providers to fully

FIGURE 13-1 Carefully assess the patient before administering a medication.

© John Moore/Staff/Getty Images News/Getty Images.

assess a patient's condition and to identify and treat life-threatening injuries and illnesses that alter homeostasis. AEMTs are often first on the scene and provide the first care for persons who need their homeostatic balance restored.

In addition to knowledge of the medications you may administer as an AEMT, you must also understand basic math for pharmacology to calculate the appropriate medication dose.

Drug doses and flow rate calculations are common areas of confusion for many prehospital personnel, yet they are skills you will need to perform frequently in the field. As an AEMT, you must learn to quickly and accurately calculate doses to maximize the chance for a positive patient outcome. Disastrous results, including death, may occur if you administer an inappropriate medication or dose, give a medication by the wrong route, or give the medication too rapidly or too slowly.

YOU are the Provider

Part 1

Your ambulance is dispatched to a local intersection for a motor vehicle crash. On arrival, you find a single vehicle that hit a telephone pole at approximately 45 miles per hour. Your patient is a 35-year-old woman seated in the driver's seat. She is responsive, alert, oriented, and complaining of severe abdominal pain. You instruct your partner to hold manual spinal motion restriction as you apply an appropriate-size cervical collar. With the assistance of the fire department responders, you extricate the patient onto a long backboard and begin your assessment.

1. On the basis of the information given, do you think this patient will require IV access?
2. What is the appropriate-size IV catheter for this patient?

Medication Administration

Medical Direction

Medication administration is governed by your local protocols and/or online medical direction. The medical director for your service may allow the administration of certain medications as long as the patient meets certain criteria. Most EMS services carry drug boxes with various cardiac medications, pain medications, anticonvulsants, antiemetics, and other medications specific to their service.

For example, for an unresponsive diabetic patient with a confirmed blood glucose reading of 40 mg/dL, the AEMT may be allowed by written protocols (standing orders) to administer 50% dextrose (D_{50}). Standing orders are a form of off-line or indirect medical control, in which the AEMT performs certain predefined procedures before contacting the physician. See Chapter 1, *EMS Systems*, for more on standing orders.

Some EMS system medical directors require AEMTs to contact them before performing certain procedures (for example, administering medications), referred to as online (direct) medical control.

Local policies and procedures are designed to guide you in specific situations. When questions or unusual situations arise, even if you function primarily by using standing orders, contact medical control for direction. *If you have any doubt as to the correct action, consult with medical control!*

The AEMT's Responsibility Associated With Drug Orders

The danger of something going wrong when administering a medication—for example, administering the wrong medication or the wrong dose of a medication—can be minimized by confirming the rights of medication administration:

- Right patient
- Right medication and indication
- Right dose
- Right route
- Right time
- Right education
- Right to refuse
- Right response and evaluation
- Right documentation

These principles are included in the following set procedure for administering any medication. These steps also incorporate several safety precautions:

1. **Obtain an order from medical control.** This order may be given to you directly, through online medical control via telephone or radio. Or it may be indirect, through protocols that contain standing orders for the administration of certain medications. For example, your system may use a protocol that describes how the medical director wants you to deal with a patient who is having respiratory difficulties. Part of this protocol may direct you to use a non-rebreathing mask to deliver oxygen to such a patient at 15 L/min. You may do this without calling online medical control if the patient meets the criteria of the protocol.

When you are communicating with medical control about administering a specific medication, make sure that the medication is indicated for the patient's condition. Knowledge of the indications, contraindications, therapeutic effects, side effects, and appropriate doses for each of the medications that you carry on your ambulance is critical to safe patient care. Given the patient's clinical presentation, you must know the right time to administer a medication (that is, when the medication is indicated). Of equal if not greater importance is knowing when not to administer a medication (that is, when the medication is contraindicated). Furthermore, some of the medications you carry on the ambulance have specific intervals for repeated doses; you must be aware of these medications and the appropriate intervals at which they are administered.

Make sure medical control understands the situation. The decision to order the administration of any given medication is complex, involving such considerations as the patient's age, weight, clinical status, allergy history, concomitant medical problems, and other drugs the patient may be taking, including prescription medications, over-the-counter (OTC) medications, and recreational drugs. Thus, it is critical that you obtain and communicate complete, accurate information about the patient to enable the physician

to make prudent, correct decisions about medication administration.

Verify that your patient is indeed the *right patient*. In situations in which there are multiple patients, reconfirm the patient's name and compare it with the wrist band or triage tag. If you are assisting a patient with medication, be sure it is prescribed to that patient.

2. **Make sure you understand the physician's orders.** If the orders are unclear or seem inappropriate for the patient's condition (for example, the dosage is more than the usual range or an unusual route of administration is requested), *ask the physician to repeat the order*. Do not assume that the physician is infallible.

3. **Repeat any orders, word for word, for verification.** This will help ensure that you understand the order and that the physician did not inadvertently give you an incorrect dosage order. In the repetition, state the *name of the medication*, the *dose*, and the *route* by which it is to be given. As an AEMT, you are just as responsible for the administration of the medication and its possible consequences as the physician giving the order, so be absolutely certain which medication is to be administered, in what dose, and by which route. If your partner does not hear the exchange of information, you should repeat the order as an additional safety measure.

4. **Inquire about any medication allergies the patient may have.** If the patient is unresponsive, try to obtain this information from another reliable source of information. Check for medic alert jewelry or tags as well.

5. **Verify the proper medication and prescription.** You have received and confirmed the medication order and determined that the patient is still a candidate for the medication. You must now make sure that the medication you are about to give is the correct medication. Carefully read the label. If it is the patient's own prescription, the bottle may show the trade name or the generic name. If you have any questions at all, contact online medical control. Examine the label to confirm that the medication is prescribed to the patient and not to a family member or friend. You should never give a medication to a patient that has been prescribed for someone

else. Note the **concentration** printed on the label.

Note that you should read the medication label at least three times before administration to ensure that you have the *right medication*:

- When it is still in the drug box it came in
- When you prepare the medication for administration
- Before actually administering the medication to the patient

6. **Verify the form, dose, and route of the medication.** At this point, you have confirmed your order and verified that the medication is correct. Now you must make sure that the form of the medication, the dose, and the route are all consistent with the order you received. For example, suppose that you are told to administer a sublingual nitroglycerin tablet. The patient's nitroglycerin bottle is empty, but he has another bottle of nitroglycerin capsules. These are to be swallowed four times per day. The medication is the same, but the form, dose, and route of delivery are different from the order given. You may not substitute the capsules for the tablets without specific orders from medical control.

You are responsible for knowing the appropriate doses for the medications you carry on your ambulance. You are also responsible for accurately calculating the appropriate dose of the medication. Always recheck your medication calculations before administration to ensure that you are administering the *right dose*.

It is imperative that you know the *right route* for the medication or medications you are about to administer. A medication given by an inappropriate route—even if it is the right medication—could have disastrous and possibly fatal consequences.

7. **Check the expiration date and condition of the medication.** The last step before administering a medication is to make sure the expiration date has not passed. Prescription and OTC medications should have an expiration date on their labels. Check the date. If no date can be found, you should examine the medication with suspicion. Check for defects in the vial, preloaded syringe, or ampule, noting whether the container appears to be cracked

or damaged. If the medication looks suspicious in any way, do *not* use it. In addition, if you find discoloration, cloudiness, or particles in a liquid medication, you should not administer it. If a patient with asthma gives you a metered-dose inhaler (MDI) and the expiration date on it is smudged, you should not administer it.

8. **Confirm medication compatibility.** If you have orders to administer more than one medication, make sure that the medications are compatible. Some medications will not mix with others, which could cause a precipitate to form in the solution. Should any cloudiness occur after a medication has been injected into IV tubing, *clamp the tubing immediately* and replace it with a new **administration set**.
9. **Dispose of any syringes and needles safely.** Do *not* try to recap a needle, for the likelihood of sticking yourself in the process is quite high; rather, immediately dispose of the needle and syringe in a sharps container.
10. **Monitor the patient for possible adverse side effects.** Reassess the vital signs, especially heart rate and blood pressure, at least every 5 minutes or as the patient's condition warrants.
11. **Document.** Always document your actions and the patient's response on the patient care report after administering a medication. Include the following:
 - Name of the medication
 - Dose of the medication
 - Time you administered the medication
 - Route of administration
 - Your name or the name of the person who administered the medication
 - Patient's response to the medication, whether positive or negative

Did the patient's condition improve, get worse, or not change at all? Were there any side effects? If your performance should ever be questioned, documentation is your best defense.

Specific Medications

Chapter 12, *Principles of Pharmacology*, lists the specific medications that a certified AEMT is allowed to administer or help patients self-administer.

Recall that as an AEMT, you may administer the following:

- Oxygen
- Oral glucose
- Glucagon
- 50% dextrose in water (D₅₀W)
- IV fluids—**D₅W** (5% dextrose in water), **normal saline**, **lactated Ringer solution**
- Epinephrine (intramuscular [IM] or subcutaneous)
- MDI medications—albuterol
- Nebulized medications—albuterol
- Nitroglycerin—spray, paste, tablets
- Nitrous oxide
- Naloxone
- Aspirin
- Others based on local protocols

Recall that you may administer or help to administer these medications only when allowed by local protocols or ordered by a licensed physician.

Basic Cell Physiology

Basic cell physiology provides an understanding of how administering fluids to a patient, for example via IV access, can be beneficial depending on the patient's condition. A human cell can exist only in a special balanced environment. Understanding how this environment is created and maintained will give you the foundation you need to determine how IV therapy will affect the patient and what is needed to protect that delicate homeostasis.

Because cells are completely enclosed by a cell membrane, compounds must move through the membrane to enter a cell. Small compounds such as water (H₂O), carbon dioxide (CO₂), hydrogen ions (H⁺), and oxygen (O₂) can easily pass through the membrane. Larger charged compounds need assistance to cross a cell membrane and enter the cell.

The composition of the cell membrane allows it to have **selective permeability**. The cell membrane is a **phospholipid bilayer**, which is an important barrier to fluid movement and the acid-base balance. Everything discussed in this section will in some way be related to the cell membrane barrier and movement across that barrier.

Electrolytes

Atoms carry charges—some positive, some negative. Two or more atoms that bond together form

a molecule. When atoms bond together, they share and disperse their charges throughout the molecule. Molecules containing carbon atoms—for example, table sugar ($C_6H_{12}O_6$)—are called organic molecules. Molecules created without carbon—for example, table salt ($NaCl$)—are called inorganic molecules. Inorganic molecules give rise to **electrolytes** when they disassociate in water into their charged components. For example, table salt disassociates into sodium (Na^+) and chloride (Cl^-).

Charged atoms and charged compounds are called electrolytes because of their ability to conduct electricity. Electrolytes, also called **ions**, are reactive and dangerous if left to circulate in the body, but the body uses the energy stored in these charged particles. Electrolytes help to regulate everything from water levels to cardiac function and muscle contractions. Water in the body helps to stabilize the electrolyte charges so that the electrolytes can be used to perform the **metabolic** functions that are necessary to life.

Each electrolyte has a unique property or value to the body and is used in a different way. If the electrolyte has an overall positive charge, it is called a **cation**; an electrolyte with an overall negative charge is called an **anion**. The major cations of the body include sodium, potassium, and calcium; conversely, bicarbonate, chloride, and phosphorus are the major anions.

Sodium (Na^+) is the principal extracellular cation needed to regulate the distribution of water throughout the body in the **intravascular** and **interstitial** fluid compartments, making it a major factor in adequate **cellular perfusion**. This gives rise to the saying, “Where sodium goes, water follows.” Sodium is also a major component of the circulating **buffer**, sodium bicarbonate ($NaHCO_3$).

Potassium is the principal intracellular cation. Approximately 98% of all the body’s potassium (K^+) is found inside the cells of the body. Potassium plays a major role in neuromuscular function as well as in the conversion of glucose into glycogen. Cellular potassium levels are regulated by insulin. The **sodium/potassium (Na^+/K^+) pump** is helped by the presence of insulin and epinephrine. Low potassium levels—**hypokalemia**—in the serum (blood plasma) can result in decreased skeletal muscle function, gastrointestinal (GI) disturbances, and alterations in cardiac function. High potassium levels in the serum—**hyperkalemia**—can result in

hyperstimulation of neural cell transmission, resulting in cardiac arrest.

Calcium (Ca^{+2}) is the principal cation needed for bone growth. It plays an important part in the functioning of heart muscle, nerves, and cell membranes and is necessary for proper blood clotting.

Low serum calcium levels—**hypocalcemia**—can result in overstimulation of nerve cells, resulting in the following signs and symptoms:

- Skeletal muscle cramps
- Abdominal cramps
- Carpopedal spasms (hand/foot spasms)
- Hypotension
- Vasoconstriction

High serum calcium levels—**hypercalcemia**—can result in decreased stimulation of nerve cells, resulting in the following signs and symptoms:

- Skeletal muscle weakness
- Lethargy
- **Ataxia**
- Vasodilation
- Hot, flushed skin

Bicarbonate (HCO_3^-) levels are related to the conditions of **acidosis** and **alkalosis** in the body. Sodium bicarbonate is the primary buffer used in all circulating body fluids.

Chloride (Cl^-) primarily regulates the **pH** of the stomach. It also regulates extracellular fluid (ECF) levels.

Finally, phosphorus (P) is an important component in the formation of adenosine triphosphate (ATP), the powerful energy supplier of the body.

Body Fluid Composition

The fluids found in the body are composed of dissolved elements and water, a combination known as a solution. A solution is a mixture of two things:

- **Solvent.** The fluid that does the dissolving, or the solution that contains the dissolved components (in the body, the solvent is water)
- **Solute.** The dissolved particles contained in the solvent

A good example of making a solution is the process of brewing a cup of coffee. Passing hot water (solvent) over the coffee grounds leaches out the oils (the solute) to create the solution known as coffee. Remember, as the solute concentration increases,

the solvent concentration decreases. Is a strong cup of coffee created by using less water (solvent) or by adding more coffee (solute)? Either one could be true, as they both end up creating stronger coffee.

Understanding the composition of body fluids will help you understand the concepts of fluid and electrolyte movement, discussed next.

Fluid and Electrolyte Movement

Water and electrolytes move among the body's fluid compartments according to some basic chemical and biologic rules. One such rule is that unequal concentrations on different sides of a cell membrane will move to balance themselves equally on both sides of the membrane. Balance across a cell membrane has two components:

- Balance of compounds (such as water or electrolytes) on either side of the cell membrane
- Balance of charges (the one or two charges carried on the atoms) on either side of the cell membrane

When concentrations of charges or compounds are greater on one side of the cell membrane than on the other, a gradient is created. The natural tendency for materials is to flow from an area of higher concentration to one of lower concentration. This movement establishes a **concentration gradient**.

The process of flowing down a gradient depends on whether the cell membrane will allow the material to pass through it. Certain compounds can travel freely across the cell membrane, whereas others require more effort to move across the membrane, either because of the size of the compound or because of an incompatible charge.

Diffusion

Compounds or charges concentrated on one side of a cell membrane will move across it to an area of lower concentration to balance themselves across the membrane, a process called **diffusion** (FIGURE 13-2). To visualize this, imagine that too many people show up for a theater performance. The management decides to open another seating area to accommodate the crowd. Patrons (charges

FIGURE 13-2 Diffusion.

YOU are the Provider

Part 2

You quickly remove the patient's clothing and find bruising around the lower abdominal area, presumably from the seat belt, with abdominal distention. The patient describes significant pain when the abdomen is palpated. Finding no other injuries, you quickly place the patient into the ambulance and initiate rapid transport to the closest Level I trauma center. A rolled-up blanket is placed under the patient's knees to help relieve some of the pressure on her abdomen.

Recording Time: 5 Minutes

Appearance	Poor
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	20 breaths/min
Circulation	Strong radial pulse; skin is cool, pale, and clammy

3. Does this patient require any medications, and, if so, by what route should they be administered?
4. What are the rights of medication administration?

FIGURE 13-3 Active transport uses energy from adenosine triphosphate (ATP) to open a pathway for compounds to move against a concentration gradient (ADP, adenosine diphosphate).

© Jones & Bartlett Learning.

or compounds) are concentrated in the small seating area (the cell) outside the door (the cell membrane) leading to the new seating area. When the theater manager opens the door, patrons can move through (selective cell membrane permeability) from the congested seating area (down a concentration gradient). The patrons spread themselves out evenly (diffuse) throughout the total area, some choosing to stay behind in the original seating area as others move into the new area, so that they all have an equal amount of room.

Filtration

Filtration is another type of diffusion, commonly used by the kidneys to clean blood. Water carries dissolved compounds across the cell membranes of the tubules of the kidney. The tubule membrane traps these dissolved compounds but lets the water pass through in much the same way that a coffee filter traps the grounds as water passes through it. This cleans the blood of wastes and removes the trapped compounds from circulation so they can be flushed out of the body.

Active Transport

Often, the cell must maintain an imbalance of compounds across its membrane to achieve some metabolic purpose. **Active transport** is a method used to move compounds to create or maintain an

imbalance of charges (**FIGURE 13-3**). An example is the sodium/potassium pump. The cell uses sodium outside the cell and potassium inside the cell for an important cellular function called **depolarization**. To maintain this imbalance, the cell must use energy in the form of ATP and actively transport compounds across its membrane. Even though active transport demands a high-energy expenditure, the benefits outweigh the initial utilization of ATP. Pumping sodium out of the cell and potassium into the cell has the added benefit of moving glucose into the cell at the same time.

Osmosis

Osmosis is movement of a solvent (water) across a cell membrane (**FIGURE 13-4**). Osmosis occurs when there are different concentrations on each side of a membrane, and equal numbers of molecules on either side are displaced to the other side. For example, if 10 sodium ions are added to the fluid surrounding a cell, this causes 10 molecules of water to be displaced from that fluid. As a result, the fluid surrounding the cell contains 10 fewer water molecules relative to the fluid within the cell, and a concentration gradient has been created. Water will then move down the concentration gradient to balance itself across the cell membrane. Essentially, osmosis is diluting a solution by adding water, whereas diffusion is moving solid particles to accomplish the same thing.

An important point to take away here is that increasing the concentration of sodium in the surrounding (extracellular) fluid decreases the water in that fluid. Water moves out of the cell to create a balance of water molecules and to dilute the increased concentrations of sodium. Remember, where sodium goes, water follows.

The movement of water adds additional molecules to the extracellular compartment to create a balanced solution. This increased, yet balanced, volume puts pressure against the cell wall, called **osmotic pressure**. Osmotic pressure drives several important metabolic functions in the body, including cellular perfusion.

FIGURE 13-4 **A.** An example of osmosis occurs when a semipermeable bag of salt water is immersed in a solution of pure water. **B.** Water moves into the bag (toward the area with lower water concentration) and sodium moves out into the water until there is an equal amount of sodium and water on each side.

© Jones & Bartlett Learning.

The effects of osmotic pressure on a cell are referred to as the **tonicity** of the solution (**FIGURE 13-5**). Tonicity is the concentration of sodium in a solution and the movement of water in relation to the sodium levels inside and outside the cell:

- An **isotonic solution** has the same concentration of sodium as does the cell. In this case, water does not shift and no change in cell shape occurs.
- A **hypertonic solution** has a greater concentration of sodium than does the cell. Water is drawn out of the cell, and the cell may collapse from the increased extracellular osmotic pressure.
- A **hypotonic solution** has a lower concentration of sodium than does the cell. Water flows into the cell, causing it to swell and possibly burst from the increased intracellular osmotic pressure.

IV fluids introduced into the circulatory system can affect the tonicity of the ECF, resulting in dire consequences unless care is used.

Fluid Compartments

The body stores water in various locations called fluid compartments. The fluid compartments are defined by their relationship to cells—the water is either inside the cell (intracellular) or outside the cell (extracellular). Although water levels in these compartments constantly shift, homeostatic control mechanisms ensure that balance is restored whenever water is lost.

The body's circulatory (vascular) system functions as a fluid highway, but it also contains

FIGURE 13-5 Tonicity.

© Jones & Bartlett Learning.

cells. Thus, it can be thought of as another fluid compartment.

The extracellular compartment is broken down into two subareas:

- **Intravascular.** The water portion of the circulatory system surrounding the blood cells (for example, in the heart, arteries, or veins)
- **Interstitial.** Water outside the vascular system and between surrounding cells (for example, between the membranes of two cells in muscle tissue)

The interstitial compartment is unique because it acts as the buffer between the other compartments. As fluid levels fluctuate between the intravascular and intracellular compartments, the interstitial compartment first responds by shifting fluid reserves between the two compartments (**FIGURE 13-6**).

Therefore, there are three fluid compartments in the human body: intravascular (extracellular), interstitial (extracellular), and intracellular. The fluids within these compartments account for 60% of total body weight.

ECF occupies any area that is not inside the cells. ECF compartments act as conduits for transferring gases and nutrients between the vascular and intracellular fluid (ICF) compartments. ECF is found in the interstitial and intravascular compartments. ECF levels in the intravascular and interstitial compartments are regulated by the presence of sodium. Interstitial fluid accounts for 16% of total body weight and occupies the microscopic spaces between the cells. Interstitial fluid consists of a

gel-type protein that helps disperse water evenly throughout the interstitial compartment. This protein gel helps move water freely between the cells and vasculature. Perfusion occurs in the capillaries as a result of high hydrostatic pressures and osmosis in the **capillary beds**. The high arterial capillary pressures placed on the capillary beds push fluids from the vascular compartment into the interstitial compartment.

ICF is within all the cells of the body. Large proteins within the cell can draw fluid into the cell because their overall negative charge attracts positively charged atoms such as potassium, sodium, and the positive end of the water molecule (H_2O). The cell membrane prevents too many positively charged compounds, including water, from entering the cell and causing it to rupture. The sodium ions drawn into the cell are quickly removed via the sodium/potassium pump to prevent cellular **lysis** (rupture of the cell).

Fluid Balance

Some form of water surrounds all cells. Cells survive as long as this environment remains stable and is compatible for the life of the cell; any alteration in the supply of water, nutrients, oxygen, or food can result in cellular death. Water exists both inside and outside the cell.

The role of water in the body is diverse; it plays a part both in cellular metabolism and in the maintenance of homeostasis. Without the presence of water in the body, people would quickly succumb to illness and disease, cellular function would cease, and body systems would shut down.

The role water plays in helping to maintain homeostasis is related to the size of the water molecule itself. Composed of only three atoms (two hydrogen and one oxygen), water has some unique properties. Water is a polar molecule; that is, it has two positive poles (hydrogen) and a negative pole (oxygen). This property means that water can surround charged particles and stabilize their charges, allowing the particles to remain in solution. Water can also move across cell membranes easily, because it is a relatively small molecule.

The body adjusts to changes in the balance between ICF and ECF by retaining or eliminating water. Fluid levels in the body are balanced when intakes equal outputs. Daily intakes of water include

FIGURE 13-6 Fluid shifts from the intravascular compartment to and from the intracellular compartment via the interstitial compartment.

fluid from liquid, food, and cellular metabolism; daily outputs occur from respiration and excretion of urine, feces, and perspiration.

Maintenance of the internal environment of the cell is regulated by elaborate systems of checks and balances. As systems in the body become imbalanced and begin to shift, feedback systems create an appropriate response to return the internal environment to normal. This normally balanced condition is referred to as homeostasis, or the resistance to change. When disturbances in homeostasis occur as a result of water shifting within the body, certain conditions may develop related to the type of shifting that occurs.

Dehydration

Dehydration is defined as depletion of the body's total systemic fluid volume. Dehydration is more common in older adults and young children. It may take days to manifest and may be a result of a medical condition. As fluid is lost from the vascular compartment, the body reacts by shifting interstitial fluid into the vascular area. This then forces a shift of fluid from the intracellular to the extracellular compartments. A total systemic fluid deficit occurs.

Signs and symptoms of dehydration include the following:

- Decreased level of consciousness (LOC)
- **Orthostatic hypotension**
- Dry mucous membranes
- **Tachycardia**
- Poor skin turgor
- Flushed, dry skin
- Decreased urine output

Causes of dehydration include the following:

- Diarrhea
- Vomiting
- GI drainage
- Hemorrhage
- Insufficient fluid/food intake
- Infection

Overhydration

When the body's total systemic fluid volume increases, overhydration occurs. Fluid fills the vascular compartment, filters into the interstitial compartment, and finally is forced from the

FIGURE 13-7 One sign of fluid backup is pitting edema, shown in this patient. Pitting edema occurs when the skin is pressed with a finger and an indentation remains after removal of the finger, as seen here.

© Medical-on-Line/Alamy Stock Photo.

engorged interstitial compartment into the intracellular compartment. This fluid backup can result in death (**FIGURE 13-7**).

Signs and symptoms of overhydration include the following:

- Shortness of breath
- Puffy eyelids
- Edema
- **Polyuria** (excessive urination)
- Moist crackles (rales)
- Acute weight gain

Causes of overhydration include the following:

- Unmonitored IV lines
- Kidney failure
- Prolonged hypoventilation

IV Fluid Composition

IV solutions are tools designed to facilitate patient treatment. Considering the cell physiology discussed thus far, the use of IV fluids can substantially alter the patient's condition. Compounds and ions dissolved in the solution are identical to the ones found in the body. Each solution is a concentration of solute and solvent.

Sodium is used as the benchmark to calculate a solution's tonicity. The concentration of sodium

in the cells of the body is approximately 0.9%. A common IV fluid that AEMTs administer is normal saline, which is 0.9% sodium chloride. Other percentages of sodium chloride may also be used. Altering the concentration of sodium in the IV solution can move the water into or out of any fluid compartment in the body. (Where sodium goes, water follows.)

Types of IV Solutions

IV solutions are categorized in two different ways. First, they are categorized as crystalloid or colloid based on their dissolved components, or makeup. Second, they are categorized as isotonic, hypotonic, or hypertonic based on their tonicity. For example, 5% dextrose in water (D₅W) is a hypotonic crystalloid solution because of its tonicity and makeup.

Crystalloid Solutions

A **crystalloid solution** contains dissolved crystals (for example, salts or sugars) in water. These solutions contain compounds that quickly dissociate in solution. The ability of these fluids to cross membranes and alter the various fluid levels makes them the best choice for the prehospital care of injured patients who need fluid replacement for body fluid loss. When you are using an isotonic crystalloid for fluid replacement to support blood pressure from blood loss, remember the 3-to-1 replacement rule: *3 mL of isotonic crystalloid solution is needed to replace 1 mL of patient blood.* This amount is needed because approximately two-thirds of the infused isotonic crystalloid solution will leave the vascular spaces in approximately 1 hour.

When you replace lost volume, it is imperative to remember that crystalloid solutions do not have the capability to carry oxygen. Boluses of 250 mL should be given to maintain perfusion (radial pulses), but not to restore blood pressure to the patient's normal level. (A **bolus** is a single dose given via the IV route.) Increasing blood pressure with IV solutions not only dilutes remaining blood volume, thereby decreasing the proportion of hemoglobin, but also may increase internal bleeding by interfering with hemostasis—the body's internal blood-clotting mechanism. Blood pressure should be titrated to 80 to 90 mm Hg systolic in adults, unless otherwise noted by local protocol.¹

Words of Wisdom

Standard IV solutions replace volume, but do not have the capacity to carry oxygen. Replace only enough lost volume to maintain perfusion, and recognize the need for rapid transport.

Colloid Solutions

A **colloid solution** contains molecules (usually proteins) that are too large to pass out of the capillary membranes and therefore remain in the vascular compartment. These large protein molecules give colloid solutions a high osmolarity. As a result, they draw fluid from the interstitial and intracellular compartments into the vascular compartments. Colloid solutions work well in reducing edema (as in pulmonary or cerebral edema) while expanding the vascular compartment. They could cause dramatic fluid shifts and place the patient in considerable danger if they are not administered in a controlled setting. Examples of colloids are albumin and hetastarch. Whole blood and blood products are also colloid solutions.

Isotonic Solutions

As mentioned, IV solutions are also categorized by their tonicity. The three categories related to tonicity are:

- **Isotonic:** 0.9% sodium chloride (normal saline), lactated Ringer
- **Hypotonic:** D₅W
- **Hypertonic:** 3.0% saline, blood products, and albumin

Isotonic solutions such as normal saline (0.9% sodium chloride) possess nearly the same **osmolarity** as serum and other body fluids. Osmolarity is technically the concentration of certain particles in a solution—the particles that influence the movement of water across a semipermeable membrane. Therefore, a solution's osmolarity indicates how easily (or not easily) water will move.

Because normal saline has similar osmolarity as serum and other body fluids, it stays inside the intravascular compartment. Isotonic solutions expand the contents of the intravascular compartment without shifting fluid to or from other compartments. Awareness of this fact is useful when

dealing with hypotensive or hypovolemic patients. Although isotonic fluid does a good job of hydrating, this fluid remains in the vascular compartment, so you must be careful to avoid fluid overloading. Patients with hypertension and heart failure are at greatest risk of fluid overload. The extra fluid increases the workload of the heart, creating fluid backup in the lungs.

Lactated Ringer solution is generally used in the field for patients who have lost large amounts of blood. It contains the buffering compound lactate, which is metabolized in the liver to form bicarbonate—the key buffer that combats the intracellular acidosis associated with severe blood loss. Lactated Ringer solution should not be given to patients with liver problems because they cannot metabolize the lactate.

D₅W is a special type of isotonic solution. As long as it remains in the bag, it is considered an isotonic solution. After administration, the dextrose is quickly metabolized, and the solution becomes hypotonic.

Hypotonic Solutions

As mentioned, hypotonic fluid has a lower concentration of sodium than the cell. When this fluid is placed in the vascular compartment, it begins diluting the serum by introducing more solvent. Soon the serum osmolarity is less than the interstitial fluid; water is pulled from the vascular compartment into the interstitial fluid compartment and, eventually, the same process is repeated, pulling water from the interstitial compartment into the cells.

Hypotonic solutions hydrate the cells while depleting the vascular compartment. These solutions may be needed for a patient on dialysis when diuretic therapy dehydrates the cells. They may also be used for hyperglycemic conditions such as diabetic ketoacidosis, in which high serum glucose levels draw fluid out of the cells and into the vascular and interstitial compartments. Hypotonic solutions can be dangerous to use because they can cause a sudden fluid shift from the intravascular space to the cells, causing cardiovascular collapse and increased intracranial pressure from shifting fluid into the brain cells. For example, giving D₅W for an extended period can cause increased intracranial pressure. Therefore, hypotonic solutions are dangerous to use with patients experiencing a stroke or any head trauma. Using hypotonic solutions on

patients with burns, trauma, malnutrition, or liver disease is also hazardous, because these patients are at risk for **third spacing**, an abnormal fluid shift into the serous linings of the body (the thick membranes that cover the organs).

Words of Wisdom

When deciding on a type of IV fluid, use the prefixes to help make the decision:

- *iso* means equal
- *hypo* means low
- *hyper* means high

We are comparing the osmolarity of the fluid to the patient's blood. An *isotonic* solution will remain in the vascular space, a *hypotonic* solution will quickly leave the vascular space, and a *hypertonic* solution will draw fluid into the vascular space.

Hypertonic Solutions

A hypertonic solution has an osmolarity higher than serum, which means the solution has more **ionic concentration** than serum and pulls fluid and electrolytes from the intracellular and interstitial compartments into the intravascular compartment. Hypertonic solutions shift body fluids into the vascular spaces and help stabilize blood pressure, increase urine output, and reduce edema. These fluids are rarely, if ever, used in the prehospital setting. Often, the term *hypertonic* refers to solutions that contain high concentrations of proteins. They have the same effect on fluid as sodium. Careful monitoring is needed to guard against fluid overloading when hypertonic fluids are used, especially in patients with impaired heart or kidney function. Also, hypertonic solutions should not be given to patients with diabetic ketoacidosis or others at risk of cellular dehydration. Hypertonic solutions have been studied in the treatment of patients experiencing hemorrhaging to help restore blood pressure while minimizing fluid overloading.

IV Techniques and Administration

The most important point to remember about IV techniques and fluid administration is to keep the IV equipment sterile. Forethought will help prevent

mental and procedural errors while starting the IV line.

One way to ensure proper technique is to develop a routine to follow as you assemble the appropriate equipment. A routine will help you keep track of your equipment and the steps necessary to complete a successful IV line.

Assembling Your Equipment

To avoid delays or the possibility of IV site contamination, gather and prepare all your equipment before you attempt to start an IV line. Sometimes the condition and presentation of the patient make full preparation difficult. This is where working as a team becomes critical. It is often the members of your own crew who, by anticipating your needs, help make the IV equipment assembly possible. Equipment includes the following components (**FIGURE 13-8**):

- Elastic constricting band (preferably nonlatex) (these are sometimes called tourniquets; not to be confused with tourniquets used for bleeding control)
- Antiseptic wipe or solution
- Gauze
- Tape or adhesive bandage
- Appropriate-size IV **catheter** (a hollow, laser-sharpened needle inside a hollow plastic tube inserted into a vein to keep the vein open)
- IV extension set
- A saline flush
- IV administration set

TABLE 13-1 shows a logical sequence of steps in assembling your equipment and performing IV therapy; each will be described later.

FIGURE 13-8 Intravenous equipment.

© Jones & Bartlett Learning.

Choosing an IV Solution

Prehospital patient care and IV therapy center on identifying the type of situation and the needs of the patient. Ask yourself the following:

- Is the patient's condition critical?
- Is the patient's condition stable?
- Does the patient need fluid replacement?

Each IV solution bag is wrapped in a protective sterile plastic bag and is guaranteed to remain sterile until the posted expiration date. After the protective wrap is torn and removed, the IV solution has a shelf life of 24 hours. The bottom of each IV bag has

TABLE 13-1 Steps in Assembling IV Equipment and Performing IV Therapy

Assembling IV Equipment

1. Always wear gloves! Standard precautions cannot be emphasized strongly enough.
2. Choose a solution. Check the solution for clarity and the expiration date and to ensure it is the correct one. Explain the procedure to the patient.
3. Choose an administration set appropriate for the needs of the patient.
4. Choose an appropriate IV site.
5. Choose an appropriate-size catheter.
6. Recheck your work before you go any further.
7. Tear tape for securing the IV site.
8. Have blood tubes close by.
9. Set up the Luer adapter and the Vacutainer barrel, or have a syringe close by for drawing blood, if indicated.
10. Have a couple of catheters ready for insertion.
11. Open an alcohol wipe.
12. Have 4 × 4-inch (10 × 10-cm) pieces of gauze ready for catching blood.
13. Have a constricting band ready.

Steps in Performing IV Therapy

1. Spike the bag and flush the line.
2. Apply a constricting band (the last thing done before inserting the IV line).
3. Insert the catheter and draw blood, if indicated.
4. Adequately dispose of sharps.
5. Hook up the IV tubing and adjust the flow.
6. Secure the site and the blood tubes.
7. Administer medication if necessary.
8. Document every procedure.

Abbreviation: IV, intravenous

© Jones & Bartlett Learning.

Street Smarts

Helpful IV therapy hints:

- Allow the hand or arm to hang off the stretcher.
- Pat or rub the area without being too firm.
- Apply chemical hot packs for approximately 60 seconds.
- If you meet resistance from a valve, elevate the extremity.
- After two misses, let your partner try.
- Try using Betadine or iodine wipes for patients with dark skin to make veins more visible.
- Try sticking without the constricting band if the vein keeps infiltrating, especially with geriatric patients.
- Never pull the catheter back over or through the needle.
- The more IVs you start, the more proficient you will become.

an **access port** for connecting the administration set. A removable pigtail that represents a point-of-no-return line protects the sterile access port. After this pigtail is removed, the bag must be used immediately or discarded.

IV solution bags come in different fluid volumes (**FIGURE 13-9**). Volumes commonly used in hospitals

FIGURE 13-9 Intravenous solution bags come in different fluid volumes.

© Jones & Bartlett Learning.

are 1,000 mL, 500 mL, 250 mL, and 100 mL; the more common prehospital volumes are 1,000 mL and 500 mL.

Choosing an Administration Set

An administration set moves fluid from the IV bag into the patient's vascular system. As with IV solution bags, IV administration sets are sterile as long as they remain in their protective packaging. Each

YOU are the Provider

Part 3

You administer oxygen to the patient by placing her on a nonrebreathing mask at 15 L/min, and after obtaining a SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury), you place an 18-gauge IV catheter in each antecubital fossa vein. The patient continues to complain of severe abdominal pain, and you notice her skin is becoming pale.

Recording Time: 11 Minutes

Respirations	20 breaths/min
Pulse	Strong and regular, 121 beats/min
Skin	Cool, pale, and clammy
Blood pressure	76/40 mm Hg
Oxygen saturation (SpO₂)	100% on 15 L/min via nonrebreathing mask
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. What type of fluid should you administer to this patient?
6. How much fluid should be administered to this patient?

Words of Wisdom

Whether the patient is a trauma patient or medical patient has nothing to do with the amount of fluid that needs to be administered. Instead, consider how much fluid the patient has lost and consider the patient's clinical presentation. Any patient who has lost a substantial amount of fluid needs rapid replacement with large-bore IV catheters. This applies to a medical patient with GI bleeding as well as a trauma patient with an unstable pelvis and bilateral femur fractures.

IV administration set has a **piercing spike** protected by a plastic cover. Again, after the piercing spike is exposed and the seal surrounding the cap is broken, the set must be used immediately or discarded.

There are different sizes of administration sets for different situations and patients. A **drip set** is another term for an administration set. Most drip sets have a number visible on the package, which indicates the number of drops it takes for 1 milliliter of fluid to pass through the orifice and into the **drip chamber** (FIGURE 13-10). Drip sets come in two primary sizes: microdrip and macrodrip. A **microdrip set** allows 60 **gtt** (drops)/mL through the small, needlelike orifice inside the drip chamber. Microdrips are ideal for medication administration or pediatric fluid delivery because it is easy to control their fluid flow. A **macrodrip set** allows 10 to 15 gtt/mL through a large opening between the

FIGURE 13-10 Drip chambers from two different-size drip sets are shown here.

© Jones & Bartlett Learning.

piercing spike and the drip chamber. Macro drip sets are best used for rapid fluid replacement.

A blood set is a special type of macrodrip set designed to facilitate rapid fluid replacement by manual infusion of either multiple IV bags or IV/blood replacement combinations. Most blood sets have dual piercing spikes that allow two bags of fluid to be hung simultaneously for the same patient (FIGURE 13-11).

Words of Wisdom

To differentiate between macrodrip and microdrip sets, remember that the prefixes refer to the size of the drops, not the size of the tubing.

Macro means *large*. A 10-gtt set, which is a macrodrip set, has 10 drops that equal 1 mL of fluid. *Micro* means *small*. A 60-gtt set, which is a microdrip set, has 60 drops that equal 1 mL of fluid.

Preparing an Administration Set

To prepare to spike the bag with the administration set, follow the steps in **SKILL DRILL 13-1**.

Special Populations

When starting an IV on a pregnant woman who may be in labor, try to avoid using the antecubital vein. Most women will need to prop on their elbows or bend their arms to pull on the bed rails while pushing, which will cut off the flow of the IV line. Choose an area on the dorsal hand or forearm for these patients.

FIGURE 13-11 Most blood sets have dual piercing spikes that allow two bags of fluid to be hung simultaneously for the same patient.

© Jones & Bartlett Learning.

Skill Drill 13-1 Spiking the Bag

Step 1

Take standard precautions. Ensure that you have chosen the correct administration set, tubing is not tangled, and protective covers are in place. Ensure you have the proper solution, that it is clear and has not expired, and that the protective tail port covers are in place. Move the roller clamp to the off (or open) position.

Step 2

Remove the protective covering found on the end of the IV bag. The bag is still sealed and will not leak until the piercing spike punctures this port. Remove the protective cover from the piercing spike (remember, this spike is sterile and sharp!) and slide the spike into the IV bag port until it is seated against the bag.

Step 3

Squeeze the drip chamber to fill to the line marking the chamber (half full) and then run fluid into the line to flush the air out of the tubing.

Skill Drill 13-1 Spiking the Bag (continued)

Step 4

Twist the protective cover on the opposite end of the IV tubing to allow air to escape. Do not remove this cover yet because the cover keeps the tubing end sterile until it is needed. Let the fluid flow until air bubbles are removed from the line before turning the roller clamp wheel to stop the flow.

© Jones & Bartlett Learning.

Step 5

Next, go back and check the drip chamber; it should be only half filled. The fluid level must be visible to calculate drip rates. If the fluid level is too low, squeeze the chamber until it fills properly; if the chamber is too full, with the roller clamp in the off (open) position, invert the bag and the chamber and squeeze the chamber to empty the fluid back into the bag. Hang the bag in an appropriate location with the end of the IV tubing easily accessible.

Choosing an IV Site

It is important to select the most appropriate vein for IV catheter insertion. Common sites for IV catheter insertion are shown in **FIGURE 13-12**. Avoid areas of the vein that contain valves because a catheter will not pass through these areas easily and the needle may cause damage. Valves can be recognized as small bumps located in the vein. Use the following criteria to select a vein:

- Locate the vein section with the straightest appearance (**FIGURE 13-13**).

- Choose a vein that has a firm, round appearance or is springy when palpated.
- Avoid areas where the vein crosses over joints.
- Avoid any extremity that shows signs of trauma, injury, or infection.
- Avoid any extremity that shows signs of edema.
- Avoid any extremity with a dialysis fistula.
- Avoid any extremity on the same side as a prior mastectomy or lymph node dissection surgery.

Also pay careful attention to areas of the vein that have track marks, because this is usually a sign

FIGURE 13-12 **A.** Common intravenous (IV) sites in the upper extremity include the brachial and cephalic veins in the arm, the distal extension of the basilic and cephalic veins in the forearm, the antecubital veins that lie anterior to the elbow, and the dorsal veins of the hands. **B.** Common IV sites in the lower extremity include the dorsal veins of the feet.

© Jones & Bartlett Learning.

of **sclerosis** (hardening of tissue) caused by frequent puncture or **cannulation** (insertion of a hollow tube into a vein).

If IV therapy is being given for a life-threatening illness or injury, choice is often limited to the areas that remain open during hypoperfusion. For patients who are in critical condition, always start at the antecubital fossa or higher. Otherwise, limit IV access to the more distal areas of the extremities. An important concept to remember is “Start distally, work proximally.” First, select areas that are as distal as possible, for example, the hand. If the distal site ruptures, or infiltrates, you can move up the extremity to the next appropriate site (for example, the forearm). Because the failed cannulation

FIGURE 13-13 Look for veins that are relatively straight and spring back when palpated.

Courtesy of Rhonda Hunt.

creates a possibility of leakage into the surrounding tissues, any fluid introduced immediately below an open wound has the potential to enter the tissue and possibly cause damage.

Large, protruding arm veins can be deceiving in their ease of cannulation. Often these bulging veins can move side to side during cannulation, causing you to miss the vein and resulting in possible **infiltration** (escape of fluid into the surrounding tissue). A remedy is to apply manual traction to the vein to lock it into position. Traction techniques differ depending on the location chosen for cannulation. Hold hand veins in place by pulling the skin over the vein taut with the thumb of your free hand as you flex the patient's hand (**FIGURE 13-14**). Stabilize wrist veins by flexing the wrist and pulling the skin taut over the vein. Applying lateral traction to the vein with your free hand can stabilize veins in the forearm and **antecubital** areas.

The patient's opinion should also be considered when selecting an IV site because the patient may know an IV location that has worked in the past.

Some protocols allow IV cannulation of leg veins. Caution must be used when cannulating these areas, because there is some thought that these might potentially place the patient at greater

FIGURE 13-14 Hold hand veins in place by pulling the skin over the vein taut with the thumb of your free hand as you flex the patient's hand.

FIGURE 13-15 A catheter is a hollow tube that is inserted into a vein to keep the vein open, allowing a passageway into the vein. This photo shows an over-the-needle catheter (needle plus catheter).

© Jones & Bartlett Learning. Courtesy of MIEMSS.

risk of infection or of **venous thrombosis** and subsequent **pulmonary embolus**.

Choosing a Catheter

The most common types of catheter found in the prehospital setting are **over-the-needle catheters** (**FIGURE 13-15**) (also called Angiocaths) and **butterfly catheters** (**FIGURE 13-16**). Catheter selection should reflect the need for IV administration, the age of the patient, and the location site.

Over-the-needle catheters are sized by their diameter, which is referred to as the **gauge**. The larger the diameter of the catheter, the smaller the gauge. Thus, a 14-gauge catheter has a greater diameter than a 22-gauge catheter. The larger the

FIGURE 13-16 A butterfly catheter is a hollow, stainless steel needle with two plastic wings to facilitate handling.

© Jones & Bartlett Learning.

Words of Wisdom

New Advanced Trauma Life Support and Prehospital Trauma Life Support recommendations include revised fluid resuscitation guidelines.² Instead of 20 mL/kg boluses of crystalloid solutions for resuscitation, they recommend 250-mL boluses with reassessment after each bolus. These boluses may be repeated up to four times prior to medical consultation. In that context, 18-gauge catheters are generally sufficient to support flow rates necessary for rapid administration of the boluses. If unsuccessful with establishment of an 18-gauge IV line in the context of hemodynamic or physiologic instability, rapid transition to intraosseous access is recommended. Establishment of a second line with an 18-gauge catheter is recommended soon after establishment of the first but without delaying transport of the patient. The purpose of the second line is redundancy of IV access and medication administration. Use of larger catheters results in increased pain for the patient, decreased likelihood of successful venous cannulation on the first attempt, and therefore likely increased scene time for patients in physiologic or hemodynamic extremis. Routine use of catheters with diameters larger than 18 gauge is therefore not recommended.

diameter, the more fluid can be delivered through the catheter.

Select the largest-diameter catheter that will fit the vein you have chosen or that will be the most appropriate and comfortable for the patient. A good rule of thumb is the more distal the IV site, the smaller the catheter. An 18-gauge catheter is usually a good size for adult patients. Metacarpal veins of

the hand accommodate 18-to 20-gauge catheters; antecubital veins of the upper arm can often accommodate larger gauge catheters.

Over-the-needle catheters can be used for all adults and most children for long-term IV therapy (**FIGURE 13-17**). The plastic catheter allows for greater patient movement and often does not require immobilizing the entire limb. Over-the-needle catheters come in different gauges as well as in different lengths. The most common lengths are 1 inch (2.5 cm) and 1¼ inches (3 cm). The shorter the catheter, the faster fluid can flow through it.

Butterfly catheters derive their name from the plastic tabs attached to the sides of the needle. These allow for a stable anchoring platform.

In recent years, an attempt has been made to create over-the-needle catheters that minimize the risk of a contaminated stick. A **contaminated stick** occurs when the same catheter that was used to cannulate the vein of a patient punctures an AEMT's skin. Newer over-the-needle catheters use several different methods to protect an AEMT from the possibility of a contaminated stick. One of the more common methods is automatic needle retraction after insertion, usually accomplished with a locking slide mechanism or a spring-loaded slide mechanism.

FIGURE 13-17 The over-the-needle sheath slides off the needle during cannulation and remains inside the vein to keep the vein open.

© Jones & Bartlett Learning.

Inserting the IV Catheter

Each AEMT has a unique technique for inserting an IV line, and it is important for you to observe many different techniques to determine what works best for you. The following considerations, however, apply to any technique:

- Keep the beveled side of the catheter up when inserting the needle in a vein (**FIGURE 13-18**).
- Maintain adequate traction on the vein during cannulation.

Apply a constricting band above the site you have chosen for the insertion to allow blood to fill the veins. A constricting band is used to help create additional vascular pressure to engorge the veins with blood below the constricting band. Constricting bands should be snug enough to substantially diminish venous flow but should not hamper arterial flow. The constricting band should be left in place only long enough to complete the IV insertion, blood draws, and line attachment. *Do not leave the constricting band applied while you assemble IV equipment.*

Words of Wisdom

Always start low and work your way up. For patients who need rapid fluid replacement or who are in cardiac arrest, the antecubital vein or one more proximal should be used.

FIGURE 13-18 Keep the beveled side of the catheter up when inserting the needle in a vein.

Courtesy of Rhonda Hunt.

Street Smarts

If you have trouble getting a catheter to feed completely, it may be against a valve. Remove the needle and attach the flush syringe or IV line to the hub of the catheter. Gently “float” the catheter into the vein as the fluid pushes the valve open. Watch carefully for infiltration around the site and if swelling is present, discontinue IV administration immediately, remove the catheter, and document the event.

Constricting bands can be difficult to manage, especially if you are wearing gloves. You should develop a technique that will allow you to release the constricting band with a small tug on one end. If a commercial device is not available, constricting bands can be made of any available material, such as the following:

- A **Penrose drain** (a type of surgical drain)
- A blood pressure cuff (**FIGURE 13-19**)
- Gloves
- Surgical tubing

After you have selected an insertion site, prep it with an alcohol swab, iodine swab, or chlorhexidine (Chloraprep). Do not touch the site after it has been prepped. Apply gentle downward or lateral traction on the vein with your free hand while holding the catheter, bevel side up, in your dominant hand. Use caution as you apply traction to avoid collapsing the vein. Begin by establishing an insertion angle of approximately 45°. Advance the catheter through the skin until the vein is pierced (there

FIGURE 13-19 A blood pressure cuff may be used in the absence of a constricting band.

Courtesy of Rhonda Hunt.

Words of Wisdom

Use an **aseptic technique** when cleansing the site (**FIGURE 13-20**). With an alcohol prep or iodine swab, start from the center of the area you intend to stick and wipe in a circular motion from the inside out. Take a second swab and wipe straight down the center over the area you intend to stick.

FIGURE 13-20 Always use an aseptic technique when cleansing the site for intravenous cannulation. Use the first alcohol pad to clean in a circular motion from the inside out, and then use the second to wipe straight down the center.

Courtesy of Rhonda Hunt.

Words of Wisdom

Using iodine to prep an IV site helps to make veins more visible in dark-skinned individuals.^{3,4}

may or may not be a flash of blood in the catheter **flash chamber**); then immediately drop the angle down to approximately 15° and advance the catheter a few more millimeters to ensure the catheter sheath is in the vein. Slide the sheath off the needle

Safety

Assume that any needle withdrawn from a patient's skin after giving an injection is contaminated with potentially infectious fluids. Handle contaminated sharps accordingly, and dispose of them immediately according to your service's procedures for preventing infectious exposures.

and into the vein; do not advance the needle too far because it can lacerate the back wall of the vein. After the catheter is fully advanced, apply pressure to the vein just proximal to the end of the indwelling catheter, remove the needle, and dispose of it in a sharps container.

Drawing Blood

AEMTs may need to draw blood when establishing IV access, depending on the patient's condition and local protocols. If blood is drawn, it must be drawn first, before fluids or medications are administered. Drawing blood, although preferable, is not always possible. Often a patient is so compromised that it is impossible to draw blood. If you are having difficulty drawing blood, stop and finish establishing the IV line. Do not allow the constricting band to remain tied too long around the patient's arm because this will allow waste products to build up in the blood and will skew lab results.

A blood collection tube with a vacuum, called a Vacutainer, connects to a catheter to assist with blood collection (**FIGURE 13-21**). Attach the Vacutainer to the hub of the catheter sheath and release the hand holding pressure because you now have a sealed system. Grasp the Vacutainer in one hand to stabilize it while you insert the tubes for the blood draws. If you do not have a Vacutainer setup, you can draw blood from the IV site using a 15- to 20-mL syringe. Follow local protocols for the types of blood tubes to draw.

Label all the tubes with the patient's name, the date, the time, and your name as soon as possible to avoid mixing tubes with those of another patient.

FIGURE 13-21 A Vacutainer.

© Jones & Bartlett Learning.

Securing the Line

After the catheter is in position, the IV line has been attached, and the contents of the IV bag are flowing properly, the site must be secured. Tape the area so that the catheter and tubing are securely anchored in case of a sudden pull on the line (**FIGURE 13-22**). You should tear the tape before you start IV administration because you will need one hand to stabilize the site while you tape the site. Double back the tubing to create a loop that will act as a shock absorber if the line gets pulled accidentally. Commercial coverings may be used in place of tape. Avoid any circumferential taping around any extremity, because circumferential taping can act like a constricting band and may impair circulation.

The steps in performing IV therapy are summarized in **SKILL DRILL 13-2**.

Changing an IV Bag

You may have to change the IV bag for some patients, particularly those who require larger volumes of IV fluid (ie, for hypovolemic shock). Do not allow an IV fluid bag to become *completely* empty. Change the bag when approximately 25 mL of fluid is left. This will reduce the risk of air embolus.

As with the initial setup of the IV bag and administration set, replacing the IV bag is a sterile process. If the equipment becomes contaminated, then replace it and use new equipment. Always ensure some fluid remains in the drip chamber and

FIGURE 13-22 Tape the area so that the catheter and tubing are securely anchored.

© Jones & Bartlett Learning.

Words of Wisdom

To further stabilize the IV line, loosely wrap it around the patient's thumb and secure it to the forearm. This will prevent disruption of the administration if the line is pulled (**FIGURE 13-23**).

FIGURE 13-23 Loosely wrap the intravenous line around the patient's thumb and secure it to the forearm.

Courtesy of Rhonda Hunt.

tubing of the set. This will prevent air from entering the patient's vein.

The steps for changing an IV fluid bag are as follows:

1. Stop the flow of fluid from the depleted bag by closing the roller clamp.
2. Prepare the new IV bag by removing the pigtail from the piercing spike port. Inspect the new bag of IV fluid for clarity and discoloration, as well as the expiration date.
3. Remove the piercing spike from the depleted bag and insert it into the port on the new bag. *Do not touch the piercing spike of the administration set.*
4. Ensure the drip chamber is appropriately filled, and then open the roller clamp and adjust the fluid rate accordingly.

Discontinuing the IV Line

To discontinue the IV line, shut off the flow from the line with the roller clamp. Gently peel the tape back toward the IV site. As you get closer to the site

Skill Drill 13-2 Obtaining Vascular Access

Step 1

Choose the appropriate fluid and examine for clarity and expiration date. Ensure that no particles are floating in the fluid and that the fluid is appropriate for the patient's condition.

Choose the appropriate drip set and attach it to the fluid. A macrodrip set (eg, 10 gtt/mL) should be used for a patient who needs volume replacement, and a microdrip set (eg, 60 gtt/mL) should be used for a patient who mainly needs a route for medication. If an IV extension set is available, attach it to the end of the tubing to assist the hospital staff in manipulating the IV tubing at the hospital.

Fill the drip chamber by squeezing it together.

(continues)

Skill Drill 13-2 Obtaining Vascular Access (*continued*)

Step 2

Flush or “bleed” the tubing to remove any air bubbles by opening the roller clamp. Make sure no errant bubbles are floating in the tubing.

Step 3

Tear tape prior to venipuncture or have a commercial device available. Collect and open antiseptic swabs, gauze pads, and anything else needed for vascular access per local practice.

Step 4

Take standard precautions before making contact with the patient. Palpate a suitable vein. Veins should be “springy” when palpated. Stay away from areas that are hard when palpated.

Step 5

Apply the constricting band above the intended IV site. It should be placed approximately 4 to 8 inches (10 to 20 cm) above the intended site.

Step 6

Clean the area using an aseptic technique. Use an alcohol pad to cleanse in a circular motion from the inside out. Use a second alcohol pad to wipe straight down the center.

Skill Drill 13-2 Obtaining Vascular Access (*continued*)**Step 7**

Choose the appropriate-size catheter, and twist the catheter to break the seal. Do not advance the catheter upward as this may cause the needle to shear the catheter. Examine the catheter and discard it if you discover any imperfections, such as “burrs” on the edge of the catheter. Loosen the catheter hub.

**Step 8**

Advise the patient to expect a needlestick. While applying distal traction at the site with one hand, insert the catheter at approximately 45° with the bevel up. This traction will stabilize the vein and help to keep it from “rolling” as you stick.

**Step 9**

Feel for a “pop” as the stylet enters the vein, and observe for “flashback” as blood enters the catheter. The clear chamber at the top of the catheter should fill with blood when the catheter enters the vein. Immediately drop the angle down to approximately 15°. If you note only a drop or two, you should gently advance the catheter farther into the vein, approximately $\frac{1}{8}$ to $\frac{1}{4}$ inch (0.3 to 0.6 cm).

Apply pressure to occlude the catheter to prevent blood leaking while removing the stylet. Place the thumb of the hand not holding the catheter over the end of the catheter that is currently situated inside the vein, so as not to pull the catheter and to prevent blood running out when you remove the needle. With practice, you will be able to feel the catheter.

**Step 10**

Immediately dispose of all sharps in the proper container.

(continues)

Skill Drill 13-2 Obtaining Vascular Access (continued)

Step 11

Attach the prepared IV line. Hold the hub of the catheter while connecting the IV line.

Step 12

Remove the constricting band.

Step 13

Open the IV line to ensure fluid is flowing and the line is patent. Observe for any swelling or infiltration around the IV site. If the fluid does not flow, check to see if the constriction band has been released. If infiltration is noted, immediately stop the infusion and remove the catheter while holding pressure over the site with a piece of gauze to prevent bleeding.

Step 14

Secure the catheter with tape or a commercial device.

Step 15

Secure IV tubing and adjust the flow rate while monitoring the patient.

FIGURE 13-24 When removing a catheter and intravenous line, pull gently and apply pressure to control bleeding.

© Jones & Bartlett Learning.

and the catheter, stabilize the catheter while you loosen all the remaining tape holding the catheter in place. Do not remove the IV tubing from the hub of the catheter. Fold a 4 × 4-inch (10 × 10-cm) piece of gauze and place it over the site, holding it down while you pull back on the hub of the catheter. Gently pull the catheter and the IV line from the patient's vein while applying pressure to control bleeding (**FIGURE 13-24**).

Alternative IV Sites and Techniques

Some additional IV sites and techniques available to prehospital providers require training beyond the scope of this chapter. However, because you may need to assist in these types of IV administration, you can benefit from understanding how they work.

Saline Locks

A **saline lock** is a way to maintain an active IV site without having to run fluid through the vein. These access devices are used primarily for patients who do not need additional fluids, but may need rapid medication delivery. Saline locks are access ports commonly used with patients who have disorders such as heart failure or pulmonary edema. A saline lock is attached to the end of an IV catheter and filled with approximately 2 mL of normal saline to keep blood from clotting at the end of the catheter (**FIGURE 13-25**). Because this is a sealed-access site, the saline remains in the port without entering the vein, thus preventing clotting. These are also known as intermittent (INT) sites because they eliminate the need to reestablish an IV line each time the patient needs medication or fluid.

FIGURE 13-25 A saline lock is attached to the end of an intravenous catheter and filled with approximately 2 mL of normal saline to keep blood from clotting at the end of the catheter.

FIGURE 13-26 External jugular vein catheterization requires a specific insertion site midway between the angle of the jaw and the midclavicular line with the catheter pointed toward the shoulder on the same side as the puncture.

Courtesy of Rhonda Hunt.

External Jugular IV Lines

External jugular IV lines provide venous access through the external jugular veins of the neck. These are the same veins used to assess jugular vein distention. The vein is tamponaded by placing a finger or the edge of a tongue depressor on the vein just above the clavicle, causing the vein to fill. If the vein is difficult to find, place the patient supine to facilitate venous return. The catheter is inserted into the vein in the same manner as a normal IV line, except the insertion point is very specific. The catheter is inserted midway between the angle of the jaw and the midclavicular line, with the catheter pointed toward the shoulder on the same side as the puncture site (**FIGURE 13-26**). These punctures are difficult because a tough, fibrous sheath that makes access difficult surrounds these veins.

These techniques require more advanced education and training than this chapter will provide. Understanding their application and use is important because you may need to perform these procedures depending on local protocols or assist with the performance of these procedures.

Words of Wisdom

Always feel very carefully for a pulse prior to cannulating an external jugular vein. It is imperative not to pierce the carotid artery.

Troubleshooting IV Therapy

Several factors can influence the flow rate of an IV line. For example, if the IV bag is not hung high enough, the flow rate will not be sufficient. It is always helpful to perform the following checks after completing IV administration. Also, if there is a flow problem, rechecking these items will help determine the cause of the problem.

- **Check your IV fluid.** Thick, viscous fluids such as blood products and colloid solutions infuse slowly and may be diluted, if needed, to help speed delivery. Cold fluids run slower than warm fluids. If you can, warm IV fluids before administering them in cold weather.
- **Check your administration set.** Macrodrrips are used for rapid fluid delivery, whereas microdrrips are designed to deliver a more controlled flow.
- **Check the height of your IV bag.** The IV bag must be hung high enough to overcome the patient's own blood pressure. Hang the bag as high as possible.
- **Check the type of catheter used.** The wider the catheter (the smaller the gauge), the more fluid can be delivered; 14 gauge is the widest,

and 27 gauge the narrowest. Catheter length also affects flow; the shorter the catheter, the more rapid the flow.

- **Check your constricting band.** One of the most overlooked factors is leaving the constricting band on the patient's arm after completing the IV line setup.

Possible Complications of IV Therapy

Problems associated with IV therapy can be categorized as either local or systemic reactions. A **local reaction** is a problem such as infiltration; phlebitis; occlusion; vein irritation; hematoma; nerve, tendon, or ligament damage; and arterial puncture. **Systemic complications** include allergic reactions, circulatory overload, air embolus, vasovagal reactions, and catheter shear.

Local IV Site Reactions

Most local reactions require that you discontinue the administration, reestablish the IV line in the opposite extremity, and document the event.

Infiltration

Infiltration is the escape of fluid into the surrounding tissue. This escape of fluid causes a localized area of edema. Some of the more common reasons for infiltration include the following:

- The IV line has passed completely through the vein and out the other side.
- The patient is moving excessively, causing the catheter to become dislodged from the vein.
- The tape used to secure the area has become loose or dislodged (again causing the catheter to become dislodged from the vein).
- The catheter was started at an angle that is too shallow and has only entered the **fascia** surrounding the vein (this is more common with IV lines in larger veins, such as those in the upper arm and neck).

Some of the associated signs and symptoms of infiltration include the following:

- Edema at the catheter site
- Continued IV flow after occlusion of the vein above the insertion point
- Patient complaints of tightness and pain around the IV site

Words of Wisdom

To document IV administration, you need to include four things:

- The gauge of the needle
- The site
- The type of fluid you are administering
- The rate the fluid is running

To correct the infiltration, discontinue administration and reestablish the IV line in the opposite extremity or at a more proximal location on the same extremity. Apply direct pressure over the swollen area to reduce further swelling or bleeding into the tissue. Avoid wrapping tape around the extremity for direct pressure because this could create a constricting band.

Thrombophlebitis

Thrombophlebitis is inflammation of the vein. Thrombophlebitis is not usually seen with the emergency prehospital patient. You may encounter it in patients who abuse drugs, as well as in patients who are receiving long-term IV therapy in a hospital, home care, or hospice setting.

Often, thrombophlebitis is associated with fever, tenderness, and red streaking up the associated vein. Hardening of the vein can occur if a vein has been repeatedly punctured, as seen with drug abuse. Some of the more common causes for thrombophlebitis include localized irritation and infection from nonsterile equipment, prolonged IV therapy, or irritating IV solutions.

Vein irritation is usually caused by an infusion that is too rapid. If redness develops at the IV site with rapidly developing thrombophlebitis, discontinue the infusion and save the equipment for later analysis. Reestablish the IV line in the other extremity with all new equipment in case there were unseen contaminants in the old equipment. Be sure to document the event and the patient's response.

Occlusion

Occlusion is the physical blockage of a vein or catheter. If the flow rate is not sufficient to keep fluid moving out of the catheter tip and if blood enters the catheter, a clot may form and occlude the flow. The first sign of a possible occlusion is a decreasing **drip rate** or the presence of blood in the IV tubing. A positional IV site can cause occlusion, which means that fluid flows at different rates depending on the position of the catheter within the vein. Proximity to a valve is often the reason for occlusion. Other causes can be related to patient movement that allows the line to become physically blocked from either resting on the line or crossing the arms. Occlusion may also develop if the IV bag nears empty and the blood pressure overcomes the flow and backs up in the line.

FIGURE 13-27 To check if an intravenous line is viable, gently flush the catheter to disrupt the occlusion and reestablish flow. This photo shows a syringe prefilled with saline.

Courtesy of Rhonda Hunt.

To determine whether an IV line should be reestablished, you may use a syringe prefilled with saline, or you may draw the saline from an IV bag. After you have a full syringe of clean IV fluid, you will use it to add pressure to the line. Gently apply pressure to the plunger to disrupt the occlusion and reestablish flow (**FIGURE 13-27**). If flow is reestablished, ensure that the line is free and the rate is sufficient. If the occlusion does not dislodge, discontinue the administration and reestablish an IV line in the opposite extremity or at a proximal location on the same extremity.

Hematoma

A **hematoma** is an accumulation of blood in the tissues surrounding an IV site. Hematomas result from vein perforation or improper catheter removal that allows blood to accumulate in the surrounding tissues. Blood can be seen rapidly pooling around the IV site, resulting in tenderness and pain and, in extreme cases, skin necrosis and slough (**FIGURE 13-28**). Patients with a history of vascular diseases (including diabetes) or patients receiving certain medications (such as corticosteroids) can have a predisposition to vein rupture or have tendencies for hematomas to develop rapidly on IV insertion.

If a hematoma develops while you are attempting to insert a catheter, stop and apply direct pressure to help minimize bleeding. If a hematoma

FIGURE 13-28 Hematomas can be caused by the improper removal of a catheter, resulting in the pooling of blood around the intravenous site, causing tenderness and pain and, in extreme cases, skin necrosis and slough.

Courtesy of Rhonda Hunt.

develops after a successful catheter insertion, evaluate the IV flow and the hematoma. If the hematoma appears to be controlled and the flow is not affected, monitor the IV site and leave the line in place. If the hematoma develops as a result of removing the IV line, apply direct pressure with a 4 × 4-inch (10 × 10-cm) gauze pad to the site.

Nerve, Tendon, or Ligament Damage

Improper identification of anatomic structures around the IV site can result in perforation of tendons, ligaments, or nerves. An IV site choice around joints increases the risk for perforation of these structures. Patients will experience sudden, severe shooting pain when a nerve, tendon, or ligament is perforated. Numbness in the extremity after the incident can be common. Immediately remove the catheter and select another IV site. Be sure to document the event.

Arterial Puncture

Occasionally, cannulation of an artery may occur. Cannulation of an artery is easily recognized because bright red blood is quickly seen either spurt-ing from the catheter after the needle is withdrawn, or backing up into the IV tubing and the IV bag because of the high pressure that exists in the arteries. If cannulation of an artery occurs, you must stop IV administration, remove the catheter, and apply direct pressure to the site with gauze for at least 15 minutes and certainly until any bleeding is controlled.

Systemic Complications

Systemic complications can develop from reactions or complications associated with IV insertion. Systemic complications usually involve other body systems and can be life threatening. If the IV line is established and patent, do not remove it, because it may be needed for treatment of the patient.

Allergic Reactions

Often, allergic reactions are minor, but anaphylaxis is possible and therefore any allergic reaction must be treated aggressively. Allergic reactions can be related to an individual's unexpected sensitivity to medication being infused with the IV fluid or to a prep solution such as iodine used to prepare the site for IV administration. Such sensitivity could be an unknown condition to the patient; thus, vigilance must be maintained with any IV line for a possible reaction.

Patient presentation depends on the extent of the reaction. Common signs and symptoms of an allergic reaction include the following:

- Itching
- Shortness of breath
- Edema of face and hands
- Urticaria
- Bronchospasm
- Anaphylaxis
- Wheezing

If an allergic reaction occurs, discontinue IV administration of the medication and remove the solution. Leave the catheter in place as an emergency medication route. Notify medical control immediately and maintain an open airway. Monitor the patient's airway, breathing, and circulation and vital signs. Document the event and keep the IV bag or medication for evaluation by the hospital. Further treatment for anaphylaxis is covered in Chapter 22, *Immunologic Emergencies*.

Air Embolus

The amount of air a healthy adult can tolerate entering the circulatory system varies, but patients who are already ill or injured can be affected if any air is introduced into the IV line. Properly flushing an IV line will help eliminate any potential of introducing air into a patient. IV bags are designed to collapse as they empty to help prevent this problem, but

collapse does not always occur. Be sure to replace empty IV bags with full ones. Entrapment of air may also occur if IV catheters in large vessels, such as external jugular veins, are left open to the air. Be sure to quickly attach the IV line to prevent such an occurrence.

If your patient begins to experience respiratory distress with unequal breath sounds, consider the possibility of an **air embolus**, an air bubble that blocks blood flow. Other associated signs and symptoms include the following:

- Cyanosis (even in the presence of high-flow oxygen)
- Signs and symptoms of shock
- Loss of consciousness
- Respiratory arrest

Treat a patient with a suspected air embolus by placing the patient on the left side with the head down to trap any air inside the right atrium or right ventricle, and rapidly transport to the closest most-appropriate facility. Be prepared to assist ventilations if the patient experiences increasing shortness of breath or inadequate tidal volume. Document the event.

Catheter Shear

Catheter shear occurs when part of the catheter is pinched against the needle, and the needle slices through the catheter, creating a free-floating segment. The catheter segment can travel through the circulatory system and possibly end up in the pulmonary circulation, causing a pulmonary embolus. Blockage of other vessels may result in a myocardial infarction, stroke, or other problems. If you suspect a catheter shear, then place the patient in a left lateral recumbent position with the legs down and the head elevated to try to keep the catheter remnant out of the pulmonary circulation.

Treatment involves surgical removal of the sheared tip. Catheter hubs are radiopaque (that is, they will appear white on a radiograph) to aid in diagnosing this type of problem. Never rethread a catheter. Dispose of the used one and use a new one.

Patients who have experienced catheter shear with pulmonary artery occlusion may present with sudden dyspnea, shortness of breath, and possibly diminished breath sounds. They will mimic the presentation of a patient with an air embolus and can be treated the same way. These patients will

need continued IV access, and you must try to obtain an IV line in the other extremity.

Circulatory Overload

An unmonitored IV bag can result in circulatory overload. Healthy adults can handle as much as 2 to 3 extra liters of fluid without compromise. Problems occur when the patient has cardiac, pulmonary, or renal dysfunction; these types of dysfunction do not tolerate any additional demands from increased circulatory volume. In trauma patients, increased circulatory volume from over-aggressive resuscitation can disrupt clot formation and increase ongoing hemorrhage. The most common cause of circulatory overload in the pre-hospital setting is failure to readjust the drip rate after flushing an IV line immediately after insertion. Always monitor IV bags to ensure the proper drip rate.

Patient presentation includes dyspnea, jugular vein distention, and increased blood pressure. Crackles are often heard when evaluating breath sounds. Acute peripheral edema can also be an indication of circulatory overload.

Words of Wisdom

When starting an IV line for the purpose of administering a medication, you should set the flow rate just slow enough to keep the vein open (TKO). A TKO rate of 8 to 15 drops per minute is sufficient to keep blood from clotting on the end of the catheter and to avoid fluid overload.

To treat a patient with circulatory overload, slow the IV rate to keep the vein open and raise the patient's head to ease respiratory distress. Administer high-flow oxygen and monitor vital signs and breathing adequacy. Contact medical control immediately and inform personnel of the developing problem because medications can be administered to reduce the circulatory volume. Document the event.

Vasovagal Reactions

Some patients have anxiety concerning needles or the sight of blood. Such anxiety may cause vasodilation, resulting in a decrease in blood pressure and patient collapse. A patient can present with anxiety, diaphoresis, nausea, and a **syncopal episode**.

Treatment for a patient with a **vasovagal reaction** (also known as vagaling down) centers on treatment for shock:

1. Place patient in the position dictated by protocol for shock management.
2. Apply high-flow oxygen.
3. Monitor vital signs.
4. Establish an IV line in case fluid resuscitation is needed.

Pediatric IV Therapy Considerations

The same IV solutions and equipment can be used on pediatric patients as on adults, with a few exceptions.

Catheters

Catheters come in various sizes (**FIGURE 13-29**). If you are using over-the-needle catheters to start a pediatric IV line, the 20-, 22-, 24-, or 26-gauge catheters are best for insertion depending on the size of the patient and the size of available veins. Butterfly catheters are ideal for pediatric patients and can be placed in the same locations as over-the-needle catheters and in visible scalp veins. Scalp veins are best used in young infants.

IV Locations

When you are starting an IV line, explain what you are doing to both the child and the parent. A parent

FIGURE 13-29 Note the difference in sizes of the catheters.

© Jones & Bartlett Learning.

can become as stressed as a child, so take time to thoroughly explain the procedure.

The younger the pediatric patient, the fewer choices you have for IV sites. Hand veins are painful and difficult to manage in younger pediatric patients but remain the location of choice for starting peripheral IV lines. Protecting the IV site after it has been established is critical and is sometimes best accomplished by immobilizing the site before cannulation with an arm board.

One of the better techniques for starting pediatric IV lines is to use a penlight to illuminate the veins on the back of the hand. Shine the light through the palm side of the hand to illuminate the veins on the back side of the hand. Be sure not to burn the patient with the penlight, even though this is unlikely. After a suitable site is located, slightly graze the surface of the hand with your fingernail so you can find the location after you turn off the penlight. Proceed with the IV insertion, using the mark you created as a guide. Sometimes the best choice is an antecubital vein line with full arm immobilization to avoid dislodging the IV line.

Scalp vein cannulation is often aesthetically unpleasant for both the child and the parents and can produce apprehension in both simply because of the location. In addition, scalp veins can be difficult to cannulate and do not allow for rapid fluid resuscitation. When you are securing a scalp vein, tape a paper cup over the site to avoid applying any direct pressure to the butterfly catheter. Pressure may cause the needle to puncture the other side of the vein and let fluids escape into the tissues (extravasation).

Geriatric IV Therapy Considerations

Smaller catheters may be preferable with older adult patients unless rapid fluid replacement is needed. Some medications commonly used by older adults have the tendency to create fragile skin and veins. Often, simply puncturing the vein will cause a massive hematoma. If this occurs, IV access may also be attempted without the use of a constricting band to reduce the incidence. The use of tape can result in skin damage, so be careful when establishing IV lines in older adults. Consider using alternative options such as paper tape or commercial devices that reduce the risk of skin damage.

FIGURE 13-30 When you are looking for an intravenous site, avoid small, spidery veins and varicose veins.

© Mark Boulton/Alamy Stock Photo.

Catheters

Try using smaller catheters (such as 20-, 22-, or 24-gauge) because they may be more comfortable for the patient and can reduce the risk of extravasation.

IV Sets

Be careful when you are using macrodrips because they can allow rapid infusion of fluids, which may result in edema if they are not monitored closely. With both geriatric and pediatric patients, fluid overloading is potentially serious. Always monitor fluid administration carefully.

Locations

In choosing an IV site, you should consider the possibility of poor vein elasticity. One of the consequences of aging is the loss of elasticity in the body tissues. Veins become sclerosed, making them brittle. Certain medications, such as prednisone, can also affect the structure of the vein, making the veins of geriatric patients even more fragile and easily ruptured. Avoid small, spidery veins that weave back and forth (**FIGURE 13-30**) because they may rupture easily. Do not use **varicose veins**; although they often appear to be ideal choices for IV starts, they are almost completely closed off and allow minimal circulation.

Intraosseous Infusion

Intraosseous (IO) means “within the bone.” IO infusion is a technique of administering fluids, blood and blood products, and medications into

FIGURE 13-31 The components of a long bone.

A. The humerus. Note the long shaft and dilated ends.

B. Longitudinal section of the humerus showing compact bone, cancellous (spongy) bone, and marrow.

© Jones & Bartlett Learning.

the **intraosseous space** of the proximal tibia, humeral head, or sternum. Long bones, such as the tibia, consist of a shaft (**diaphysis**), the ends (**epiphyses**), and the growth plate (**epiphyseal plate**) (**FIGURE 13-31**).

The IO space collectively comprises the spongy cancellous bone of the epiphyses and the medullary cavity of the diaphysis. Its vasculature drains into the central circulation by a network of venous sinuses and canals.

When a patient is in shock, cardiac arrest, or an otherwise hemodynamically compromised condition, peripheral veins often collapse, making IV access extremely difficult, if not impossible. However, the IO space remains patent unless trauma has been sustained to its bony structure (eg, a fracture). For this reason, the IO space is commonly referred to as a “noncollapsible vein.” It quickly absorbs IV fluids and medications and rapidly gets them to the central circulation—as rapidly as is possible with

TABLE 13-2 Flow Rate for Various IO Sites

IO Site	Reported Flow Rate (mL/min)
Sternal	469
Humeral	148.1–286
Proximal tibial	154–204.6

Abbreviation: IO, intraosseous

Data from: Pasley J, Miller CHT, DuBose JJ, et al. Intraosseous infusion rates under high pressure: a cadaveric comparison of anatomic sites. *J Trauma Acute Care Surg.* 2015;78(2):295–299; Ngo ASY, Oh JJ, Chen Y, et al. Intraosseous vascular access in adults using the EZ-IO in an emergency department. *Int J Emerg Med.* 2009;2(3):155–160; and Ong MEH, Chan YH, Oh JJ, Ngo AS-Y. An observational, prospective study comparing tibial and humeral intraosseous access using the EZ-IO. *Amer J Emerg Med.* 2009;27:8–15.

the IV route. Anything that can be given via the IV route—crystalloids, medications, and blood and blood products—can be given via the IO route.

IO infusion is indicated when you are unable to rapidly obtain IV access in a critically ill or injured patient (eg, in profound shock, cardiac arrest, or status epilepticus). Depending on local protocol, you will typically attempt one or two IV lines within 90 seconds prior to an IO infusion attempt. Some situations, such as cardiac arrest, may warrant going immediately to an IO infusion due to the time savings, likelihood of success, and ease of use. Vascular access times and flow rates for various IO sites are presented in **TABLE 13-2**.

IO Sites

Common sites you will use for IO insertion are the sternum, proximal humerus, proximal tibia, and distal tibia. The technique for performing IO infusion requires proper anatomic landmark identification. To locate the humeral IO site, you will need to manipulate the patient's arm and palpate the humeral head (**FIGURE 13-32**). Begin by placing the patient's hand over the abdomen, which causes an internal rotation of the humeral head. Place the ulnar aspect of one of your hands vertically over the axilla near the humeral head that will be used for insertion. Place the ulnar aspect of your other hand laterally along the midline of the upper portion of the patient's humerus with the fingers pointing toward the head. Place your thumbs together, palpating up the surgical neck to the humeral head. When this site is used, medications can reach the right atrium within 3 seconds of rapid IV push. Appropriate needle selection and stabilization are crucial to use this site successfully.

FIGURE 13-32 The humeral site for intraosseous insertion.

FIGURE 13-33 The sternal site for intraosseous insertion.

Courtesy of Stephen J. Rahm, NRP.

Identify the sternal IO site by palpating the sternal notch and using the IO device's adhesive target (**FIGURE 13-33**). The sternal site has an extremely rapid flow rate. The device location is near the chest compression landmarks; however, the device does not impede chest compressions.

The flat bone of the proximal tibia is located medial to the tibial tuberosity, the bony protuberance just below the knee. It is necessary to

FIGURE 13-34 The proximal tibia site for intraosseous insertion in adults.

© Jones & Bartlett Learning.

FIGURE 13-35 The distal tibia site for intraosseous insertion in adults.

© Jones & Bartlett Learning.

feel the leg to know the difference between the first and second landmarks (these cannot be seen; they must be felt). To locate the proximal tibia IO site, palpate the tibial tuberosity, then palpate 0.75 inch (2 cm) medially. This is the site for adult patients (**FIGURE 13-34**). For pediatric patients, palpate 0.4 to 0.75 inch (1 to 2 cm) distally to avoid the epiphyseal plate.

For the distal tibia IO site, use palpation as well. First, identify the medial malleolus. Then palpate 0.75 to 1.2 inches (2 to 3 cm) above that site (**FIGURE 13-35**). For pediatric patients, you should palpate 0.4 to 0.75 inch (1 to 2 cm) above the medial malleolus.

Equipment for IO Infusion

Several products are used for placing an IO needle into the IO space: manually inserted IO needles, the

FIGURE 13-36 Manually inserted intraosseous needles.

© Jones & Bartlett Learning.

FAST1, the EZ-IO, the Bone Injection Gun (BIG), and the New Intraosseous (NIO) device. Use of these devices requires specialized training and thorough familiarity with each device's features, functionality, and clinical application.

If your EMS system uses any of these devices, then follow local protocols regarding their application. Manually inserted IO needles (ie, Jamshedi needle, Cook catheter) were the original devices used for establishing IO access in children and are still widely used in the prehospital setting. They consist of a solid boring needle (**troc**ar) inserted through a sharpened hollow needle (**FIGURE 13-36**). The IO needle is pushed into the bone with a screwing, twisting action. After the needle pops through the bone, the solid needle is removed, leaving the hollow steel catheter in place. The IV tubing is attached to this catheter. Because manually inserted IO needles are long, rest at a 90° angle to the bone, and are easily dislodged, they require full, careful immobilization. Stabilization is critical for these lines to maintain adequate flow. Stabilize the IO needle in the same manner that you would any impaled object.

FAST Devices

The **FAST devices** (First Access for Shock and Trauma) were the first IO devices approved for use in patients age 12 years and older. Four design elements allow IO placement in the sternum using FAST devices: an infusion tube and subcutaneous portal, an introducer, a target/strain relief patch, and a protective dome. FAST devices can be used during cardiac arrest. Although chest compressions can coincide with FAST IO use, mechanical

FIGURE 13-37 The FAST1 intraosseous insertion device.
© Pynq Medical Corporation.

cardiopulmonary resuscitation (CPR) devices must be paused during the insertion phase. Mechanical CPR can continue after the FAST device is stabilized.

The company that developed the FAST devices chose sternum placement based on the ease of locating the manubrium and because it is easier to penetrate than other bones. The landmarks can be felt on most adults even in low-light situations. The target device is shaped so that it lines up with the sternal notch, minimizing the margin of error.

The FAST1 is the original sternal IO device (**FIGURE 13-37**). It consists of a 14-gauge infusion tube and 10 stabilization needles. It has been field tested in the military and used in civilian EMS for over a decade. The device is completely manual (no batteries required).

The FAST Responder (FASTR) is an updated device that has some advantages. Many of the components are already assembled, expediting the insertion process. For example, the adhesive target comes attached to the device. The device also has a safety lock that must be removed before insertion. The FASTR only requires 32 pounds (15 kg) of pressure for insertion. If sternal IOs are the preference for your EMS system, then familiarize yourself with both devices.

Both devices are designed to remain in place for a maximum of 24 hours. To remove either FAST device, firmly grasp the insertion tube and pull steadily until the device is dislodged. Use one continuous motion for removal; avoid starting and stopping.

EZ-IO Device

The **EZ-IO** features a handheld battery-powered driver, to which a special IO needle is attached (**FIGURE 13-38**). This device is used to insert an IO needle into the proximal or distal tibia of adults and children and the humeral head in adults when IV access is difficult or impossible to obtain. The battery-powered driver of the EZ-IO is universal,

FIGURE 13-38 The EZ-IO insertion device features a handheld battery-powered driver, to which a special intraosseous needle is attached. The battery-powered driver of the EZ-IO is universal, but different sizes of needles are available.

Data from: Arrow EZ-IO Intraosseous Vascular Access. EZ-IO Intraosseous Vascular Access Needles: Instructions for Use. 8082 Rev A. July 2014. http://www.teleflex.com/en/usa/ezioeducation/documents/8082_Rev_A_US_FDA_Intraosseous_Infusion_System_IFU.pdf. Accessed February 15, 2017.

but different sizes of needles are available depending on the patient. The needle size is estimated based on the insertion site and patient's weight; however, the ultimate determining factor in needle size selection is the amount of subcutaneous tissue present over the insertion site (**TABLE 13-3**). When sizing the needle, you should ensure at least one hash mark (5 mm) can be seen after insertion.

FIGURE 13-39 The Bone Injection Gun (BIG).

Courtesy of PerSys Medical.

Use a 10-mL syringe to remove an EZ-IO. Attach the syringe to the IO Luer lock, twist the syringe clockwise, and pull the device out in one swift motion.

Bone Injection Gun Device

The **Bone Injection Gun (BIG)** is a spring-loaded device that is used to insert an IO needle into the proximal tibia of adult and pediatric patients and the humeral head in adults (**FIGURE 13-39**). It comes in an adult size and a pediatric size. Although both versions offer the same operational features, the depth of insertion is different for the adult and pediatric devices.

The BIG uses the safety lock as the stabilization device after the device has been inserted. When you are ready to remove the device, use the stabilization device as the removal tool. Place the wider side of the removal tool over the connection port. Pull the device out in one swift motion while grasping onto the removal tool.

New Intraosseous Device

The **New Intraosseous (NIO) device** is a device that is placed in the proximal tibia of an adult patient (**FIGURE 13-40**). The humeral head is an alternative site for this device. The spring-loaded device contains neither drill nor battery. It is inserted by unlocking a safety cap. While applying downward pressure with the dominant hand, the fingers of the other hand are used to pull trigger wings up to deploy the device. The device is then pulled up in a rotating motion while the needle stabilizer is held

FIGURE 13-40 The New Intraosseous (NIO) device.

Courtesy of PerSys Medical.

against the skin. After the introducing trocar is removed, any Luer-lock tubing can be attached.

A pediatric version, NIO Pediatric (NIO-P), is also available. This device has an adjustable dial, allowing the provider to adjust by age or depth (if excessive girth for the age is anticipated). At the time of this writing, the NIO-P is approved for placement in the proximal tibia only.

Performing IO Infusion

Follow these steps to perform IO infusion using an EZ-IO device **SKILL DRILL 13-3**.

To attach a FAST1 device, follow these steps:

1. Align the adhesive target on the patient and prepare to insert the device into the manubrium. The manubrium is approximately 15 mm below the sternal notch, and at 13.3 mm, it is the thickest part of the sternum. The stabilization needles prevent you from pushing the insertion tube to an inappropriate depth.
2. Prepare the insertion site on the patient's manubrium.
3. Position yourself behind the patient's head, place two hands on the FAST1 device, align the stabilization needles with the target, and apply approximately 45 pounds (20 kg) of pressure until you feel the infusion tube separate from the FAST1 introducer (**FIGURE 13-41**).
4. Discard the stabilization needle in a sharps container and attach the IV tubing to the insertion tube's Luer lock. Aspirate blood and particles of bone marrow to ensure proper placement. Slowly inject the IV solution to ensure proper placement of the needle. Adjust the flow rate as appropriate. Place the protective dome, and begin using the device.

Skill Drill 13-3 Gaining IO Access With an EZ-IO Device

Step 1

Check the selected IV fluid for proper fluid, clarity, and expiration date. Look for discoloration and for particles floating in the fluid. If particles are found in the fluid, discard the bag and choose another bag of fluid.

Select the appropriate equipment, including an IO needle, syringe, saline, extension set, antiseptic swabs, and gauze pads.

A three-way stopcock may also be used to facilitate easier fluid administration.

Select the proper administration set. Connect the administration set to the bag. Prepare the administration set. Fill the drip chamber and flush the tubing. Ensure all air bubbles are removed from the tubing.

Prepare the syringe and extension tubing. Ensure the tubing is not tangled.

Cut or tear the tape and prepare bulky dressings. This can be done at any time before IO puncture.

Step 2

Take standard precautions.

Step 3

Identify the proper anatomic site for IO puncture. Palpate the landmarks and then prepare the site.

- **Tibia placement.** This site is reserved for the EZ-IO and the BIG.
- **Humerus placement.** Humeral placement is typically reserved for adults when using the EZ-IO or the BIG.

Step 4

Cleanse the site appropriately. Follow aseptic technique by cleansing in a circular manner from the inside out.

Skill Drill 13-3 Gaining IO Access With an EZ-IO Device (continued)

Step 5

Attach the needle to the EZ-IO gun and remove the protective cover. Examine the needle. If you find any imperfections, discard the needle and select another one.

Step 6

Perform the IO puncture by first stabilizing the tibia, then placing a folded towel under the knee, and finally holding the extremity in a manner to keep your fingers away from the site of puncture. For humeral placement, continue to apply pressure on the anterior and inferior aspects of the humerus. Insert the needle at a 90° angle to the insertion site. Advance the needle with a twisting motion until a “pop” is felt. Unscrew the cap, and remove the stylet from the needle.

Step 7

Remove the stylet from the catheter.

Step 8

Attach the syringe and extension set to the IO needle. Pull back on the syringe to aspirate blood and particles of bone marrow to ensure proper placement. The absence of marrow does not mean the access failed. Check the site for other signs of extravasation.

Slowly inject saline to ensure proper placement of the needle. Responsive patients should receive 1% lidocaine prior to infusion of fluids. Watch for extravasation, and stop the infusion immediately if any evidence of extravasation is noted. It is possible to fracture the bone during insertion of the IO needle. If this happens, then remove the IO needle and switch to the other insertion site.

Connect the administration set and adjust the flow rate as appropriate. Fluid does not flow as rapidly through an IO catheter as through an IV line; therefore, crystalloid boluses should be given with a syringe in children and a **pressure infuser device** (a sleeve placed around the IV bag and inflated to force fluid from the IV bag) in adults.

Secure the needle with tape, and support it with a bulky dressing. Stabilize in place in the same manner that an impaled object is stabilized. Use bulky dressings around the catheter, and tape securely in place. Be careful not to tape around the entire circumference of the leg because this could impair circulation and potentially result in compartment syndrome.

Dispose of the needle in the proper container.

FIGURE 13-41 To use the FAST1 device, first align the adhesive target along the patient's sternal notch, and match the insertion site with the patient's manubrium. Position yourself behind the patient's head, place your hand on the FAST1 device, align the stabilization needles with the target, and apply pressure until you feel the infusion tube separate from the FAST1 introducer.

© Jones & Bartlett Learning.

Potential Complications of IO Infusion

If the proper technique is used (ie, proper anatomic landmark identification, aseptic technique), then IO infusion is associated with a relatively low complication rate. The same potential complications associated with IV therapy—thrombophlebitis, local irritation, allergic reaction, circulatory overload, and air embolism—can occur with IO infusion, as well as several others unique to this method of infusion.

Extravasation occurs when the IO needle does not rest in the IO space, but rather rests outside the bone (because the bone was missed completely or is fractured or because the needle becomes dislodged from the bone). In such a case, IV fluid will collect in the soft tissues. The risk of extravasation can be reduced substantially by using the proper insertion technique: *insert the IO needle at a 90° angle to the bone*. Extravasation should be suspected if the infusion does not run freely or if the site—especially the posterior aspect of the leg—rapidly becomes edematous. If this occurs, discontinue the infusion immediately and reattempt insertion in the opposite leg. Undetected extravasation could result in compartment syndrome.

Osteomyelitis is inflammation of the bone and muscle caused by an infection. Osteomyelitis can occur from IO insertion, but is rare.

Failure to identify the proper anatomic landmark can damage the growth plate, potentially resulting in long-term bone growth abnormalities in children. If your insertion technique is too forceful, or if you use an IO needle that is too large for the patient's age or size, then fractures can occur. Through-and-through insertion occurs when the IO needle passes through *both* sides of the bone. To avoid this, stop inserting the needle when you feel a pop. If you feel a “pop, pop,” then you have likely passed the needle through both sides of the bone. If either occurs, then remove the needle and attempt insertion on the opposite extremity.

A pulmonary embolism can occur if particles of bone, fat, or marrow enter into the systemic circulation and lodge in a pulmonary artery. You should suspect a pulmonary embolism if the patient experiences acute shortness of breath, pleuritic chest pain, and cyanosis.

Words of Wisdom

Except for the FAST1 sternal IO device, all IO devices (manual, spring-loaded, and battery-powered) are primarily used to insert an IO needle into the IO space of the proximal tibia, distal tibia, or humeral head. However, other anatomic locations, such as the distal femur, may also be acceptable locations for IO needle insertion.

Contraindications to IO Infusion

Cannulation of a peripheral vein remains the preferred route for administering IV fluids and medications. If a functional IV line is available, in a pediatric patient or an adult, IO cannulation is *not* indicated. Other contraindications to IO cannulation and infusion include fracture of the bone intended for IO cannulation, osteoporosis, **osteogenesis imperfecta** (a congenital disease resulting in fragile bones), bilateral knee replacements (humeral and sternal sites remain an option), and a prosthetic limb at the IO site.

Mathematical Principles Used in Pharmacology

As mentioned, you will need an understanding of some basic mathematical principles to calculate accurate medication dosages. This section reviews

some basic principles and discusses formulas for medication calculations.

Mathematical Principles Used in Pharmacology

Mathematics Review

This section discusses the use of fractions, percentages, and decimals. Having basic math skills is imperative for appropriate medication administration.

Understanding fractions is important in formula calculation. Fractions represent a portion of a whole number expressed. Fractions are expressed as a numerator (the top number representing the portion available) over the denominator (representing the total quantity). For example, if you have four EMS units available and one of them is dispatched to an emergency, then one-fourth ($\frac{1}{4}$) of your units are occupied. Think of fractions as the numerator divided by the denominator. For example, $\frac{1}{4}$ is the same as $1 \div 4$.

Decimals distinguish numbers that are greater than zero from numbers that are smaller than zero. Whole numbers appear to the left side of the decimal point, and fractions of numbers on the right. Fractions can be easily converted to decimals by dividing the numerator by the denominator. For example, when you are administering atropine to bradycardic adult patients, you administer $\frac{1}{2}$ of 1 milligram. By dividing 1 by 2, you get 0.5 ($1 \div 2 = 0.5$).

Dividing or multiplying by 10 is simple when you remember the following method: If you are dividing a number by 10, then simply move the decimal point to the left; if you are multiplying a number by 10, then simply move the decimal point to the right. In other words, if you are dividing the number 20 by 10, moving the decimal point one space to the left results in 2, which is the correct answer. The following examples show this method.

Multiplication problem: 20×10

Step 1: Place the decimal point:

20.0

Step 2: To multiply by 10, move the decimal point one space to the right:

200.0

The answer is 200.

Division problem: $20 \div 10$

Step 1: Place the decimal point:

20.0

Step 2: To divide by 10, move the decimal point one space to the left:

2.00

The answer is 2.

Percentages are a part of 100 and are denoted by the % symbol. Percentages can be represented as a fraction with the denominator being 100; for example, $21\% = 21/100$. Decimals can also be turned into percentages easily by moving the decimal point over two places (0.21 is equal to 21%).

The Metric System

The **metric system** is a decimal system based on multiples of 10. It is used to measure length, volume, and weight, which are represented as follows:

- Meter (m): The basic unit of length
- Liter (L): The basic unit of volume
- Gram (g): The basic unit of weight

In the metric system, prefixes demonstrate the fraction of the base being used. Commonly used prefixes, from smallest to largest, include the following:

- micro- = 0.000001
- milli- = 0.001
- centi- = 0.01
- kilo- = 1,000

TABLE 13-4 illustrates the symbols of weight and volume used in the metric system. It is important to be able to recognize these symbols because medications will be supplied in a variety of weights and volumes and you will be required to convert these weights to volume to administer the appropriate dose of a medication to your patient.

TABLE 13-5 illustrates the metric units of weight and volume and their equivalents. Again, you must be able to understand these metric unit equivalents for proper drug conversion and subsequent administration.

To administer the appropriate dose of a medication to a patient, you must be able to convert larger units of volume to smaller ones (for example,

TABLE 13-4 Symbols Used in the Metric System

Unit	Symbol
Weight (smallest to largest)	
Microgram	mcg
Milligram	mg
Gram	g (or gm)
Kilogram	kg
Volume (smallest to largest)	
Milliliter	mL
Deciliter	dL
Liter	L

© Jones & Bartlett Learning.

liters to milliliters) and larger units of weight to smaller ones (for example, grams to milligrams). Conversely, you must also be able to convert smaller units of volume to larger ones (for example, milliliters to liters) and smaller units of weight to larger ones (for example, milligrams to grams).

TABLE 13-5 Metric Units

Unit	Equivalent
Weight (smallest to largest)	
1 mcg	0.001 mg
1 mg	1,000 mcg
1 g	1,000 mg
1 kg	1,000 g
Volume (smallest to largest)	
1 mL	1 cc ^a
100 mL	1 dL
1,000 mL	1 L

^a Cubic centimeters (cc) is a unit also used to represent milliliters (mL); therefore, 1 cc is the same as 1 mL (1 cc = 1 mL).

© Jones & Bartlett Learning.

Medications are packaged in different units of volume and weight; however, the volume (for example, milliliters) and weight (for example, micrograms, milligrams, grams) of the medication to be administered is usually only a fraction of the total amount of its packaged form. For example, a physician may order 50 mg of a medication for a patient,

YOU are the Provider

Part 4

You administer an initial 250-mL bolus of 0.9% normal saline. After the initial fluid bolus is infused, you recheck her blood pressure and breath sounds. You find no increase in her blood pressure, and breath sounds remain clear, so you administer another 250-mL bolus of 0.9% normal saline. On arrival at the trauma center, you turn over care to the awaiting trauma team without incident.

Recording Time: 21 Minutes

Respirations	20 breaths/min
Pulse	Strong and regular, 130 beats/min
Skin	Cool, pale, and clammy
Blood pressure	86/48 mm Hg
Oxygen saturation (SpO₂)	100% on 15 L/min
Pupils	PERRLA

7. Why is it important to constantly reassess breath sounds when you are administering fluid to a patient?
8. What are some possible complications of vein cannulation?

but the medication is packaged in grams. Therefore, you must be able to convert grams to milligrams and then determine how much volume is required to achieve the desired dose. (**Desired dose** refers to the amount of a medication that the physician orders, or protocol dictates, you to give to a patient.)

Volume Conversion

In the prehospital setting, you will usually be dealing with only two measurements of volume: milliliters and liters. Because 1 L equals 1,000 mL, simply divide or multiply by 1,000 or move the decimal point three places to the left or right.

When you are converting milliliters to liters, divide the smaller unit of volume by 1,000 *or* simply move the decimal point three places to the left, as demonstrated in the following examples:

Example 1:

Converting 100 mL to L (100 mL = X L)

$$100 \text{ mL} \div 1,000 = 0.1 \text{ L or } 100. = 0.1 \text{ L}$$

←

Example 2:

Converting 250 mL to L (250 mL = X L)

$$250 \text{ mL} \div 1,000 = 0.25 \text{ L or } 250. = 0.25 \text{ L}$$

←

Conversely, when you are converting liters to milliliters, multiply the amount in liters by 1,000 *or* simply move the decimal point three places to the right, as demonstrated in the following examples:

Example 1:

Converting 1.5 L to mL (1.5 L = X mL)

$$1.5 \text{ L} \times 1,000 = 1,500 \text{ mL or } 1.500 = 1,500 \text{ mL}$$

→

Example 2:

Converting 25 L to mL (25 L = X mL)

$$25 \text{ L} \times 1,000 = 25,000 \text{ mL or } 25.000 = 25,000 \text{ mL}$$

→

Weight Conversion

You will likely only need to convert weight when assisting a paramedic with administering a medication to a pediatric patient. Converting weight from

g to mg is simply a matter of multiplying or dividing by 1,000 or moving the decimal point three places to the right or left. To convert g to mg, multiply the larger unit of weight by 1,000 *or* simply move the decimal point three places to the right, as demonstrated in the following examples:

Example 1:

Converting 2 g to mg (2 g = X mg)

$$2 \text{ g} \times 1,000 = 2,000 \text{ mg or } 2.000 = 2,000 \text{ mg}$$

→

Example 2:

Converting 5 mg to mcg (5 mg = X mcg)

$$5 \text{ mg} \times 1,000 = 5,000 \text{ mcg or } 5.000 = 5,000 \text{ mcg}$$

→

Words of Wisdom

When you are converting units of volume, remember these basic rules:

Volume conversion

Smaller to larger (for example, mL to L): Divide the smaller unit by 1,000 or move the decimal point three places to the left.

Larger to smaller (for example, L to mL): Multiply the larger unit by 1,000 or move the decimal point three places to the right.

Conversely, to convert a smaller unit to a larger unit when the difference is 1,000 (such as milligrams to grams or micrograms to milligrams), divide the mg by 1,000 *or* simply move the decimal point three places to the left, as demonstrated in the following examples. Remember that 1 g equals 1,000 mg and 1 mg equals 1,000 mcg.

Example 1:

Converting 200 mcg to mg (200 mcg = X mg)

$$200 \text{ mcg} \div 1,000 = 0.2 \text{ mg or } 200. = 0.2 \text{ mg}$$

←

Example 2:

Converting 250 mg to g (250 mg = X g)

$$250 \text{ mg} \div 1,000 = 0.25 \text{ g or } 250. = 0.25 \text{ g}$$

←

Converting Pounds to Kilograms

It would be a luxury if your patients were able to tell you how much they weighed in kilograms (kg); however, the chances of this happening are slim to none. For patients who do not know their weight in pounds or who are unresponsive and unable to provide you with this information, you must do the following:

1. Estimate the patient's weight in pounds (lb)
2. Convert pounds to kilograms (kg)

Although many of the medications given in emergency medicine are administered in a standard dose (for example, 1 mg of epinephrine), other paramedic-level medications are administered based on the patient's weight in kilograms (for example, 1 to 1.5 mg/kg of lidocaine). In addition, most medications administered to pediatric patients are based on their weight in kilograms.

There are two formulas that can be used to convert pounds to kilograms; use the one that is easiest for you to remember.

Formula 1:

Divide the patient's weight in pounds by 2.2
(1 kg = 2.2 lb)

For example, when converting a 170-lb man's weight to kilograms, the formula would be as follows:

$$170 \text{ lb} \div 2.2 = 77.27 \text{ kg}$$

Because the value following the decimal point in the preceding example is less than 0.5, you may round the patient's weight in kg to 77.0. If the value after the decimal point had been greater than 0.5, you would round the weight in kg to 78.0. Although this may seem negligible, it is important to administer the most appropriate amount of the medication to the patient; it's good practice.

Formula 2:

Divide the patient's weight in pounds by 2
and subtract 10%

For example, when converting a 120-lb woman's weight to kg, the formula would be as follows:

$$\text{Step 1: } 120 \text{ lb} \div 2 = 60 \text{ lb}$$

$$\text{Step 2: } 60 \text{ lb} \times 10\% = 6$$

$$\text{Step 3: } 60 - 6 = 54 \text{ kg}$$

Calculating Drip Rates

As an AEMT, you will sometimes administer IV fluid, such as normal saline, lactated Ringer solution, or D₅W. IV fluid hydrates the patient and may treat shock, but it does not include medication. When you administer IV fluid, you will need to calculate the drip rate.

One of the easiest ways to calculate drip rates is to use dimensional analysis. Dimensional analysis uses the same simple conversions as equations, and you will not need to memorize the equation! Dimensional analysis allows you to compare seemingly unrelated items by setting up a relationship (that is, a comparison between two items).

An example of a relationship could be a car and the wheels on a car. Every car rides on four wheels, so there are four wheels for every car.

$$\frac{1 \text{ car}}{4 \text{ wheels}} = \frac{4 \text{ wheels}}{1 \text{ car}}$$

Another way to look at these comparisons is as a ratio, which is by nature a relationship. Dimensional analysis uses ratios as conversion factors.

To calculate a drip rate, you need to know:

- Which administration set to use
- Length of time for the infusion
- Amount to flow

You may need the conversion factor of 1 hour equals 60 minutes.

Example: Determine how many drops per minute should be given using the following information:

- Order given is for 250 mL normal saline over 90 minutes.
- Administration set 5 macrodrip (10 gtt/mL).

Set up the equation:

$$\frac{? \text{ gtt}}{\text{min}} = \frac{10 \text{ gtt}}{1 \text{ mL}} \times \frac{250 \text{ mL}}{90 \text{ min}}$$

Cancel out what you can and reduce the fractions:

$$\frac{? \text{ gtt}}{\text{min}} = \frac{1\cancel{0} \text{ gtt}}{1 \cancel{\text{mL}}} \times \frac{250 \cancel{\text{mL}}}{9\cancel{0} \text{ min}}$$

Multiply and divide:

$$= \frac{250 \text{ gtt}}{9 \text{ min}} = \frac{27.77 \text{ gtt}}{\text{min}} = 28 \text{ gtt/mL}$$

You will need to set the drip rate at 28 gtt/min normal saline to achieve the desired order.

Another useful formula to remember is a simple drip rate calculation that gives you the number of drops per minute:

$$\frac{(\text{volume in mL}) \times (\text{drip set})}{(\text{time in minutes})} = \frac{\text{gtt}}{\text{min}}$$

Words of Wisdom

The volume in milliliters (mL) is the “doctor’s order.” The drip set is always drops per mL, and the time is always in minutes. Multiply the doctor’s order (in mL) times the drip set (in drops/mL) and divide by the time (in minutes). This yields the number of drops per minute.

Calculating Medication Doses

When you administer a medication, you will need to calculate the dose. There are multiple formulas for calculating medication doses. It is beyond the scope of this chapter to demonstrate every one of these calculation formulas. Therefore, this chapter is limited to formulas that most students find easy to understand. For other calculation formulas, consult with your instructor. The method of drug dose calculation demonstrated in this chapter is based on the following three factors:

1. Desired dose
2. Concentration of the medication available (dose on hand)
3. Volume to be administered

Desired Dose

The desired dose (that is, the drug order) is the amount of a medication that the physician orders you to administer to a patient. It may be expressed as a standard dose (for example, 25 g of dextrose), or it may be expressed as a specific number of grams or milligrams per kilogram of body weight (for example, 0.1 mg/kg is the pediatric dose for naloxone).

Medication Concentration

After receiving a drug order (that is, the desired dose), you must determine how much of the medication you have available. In other words, you must know its *concentration*—the total weight (micrograms, milligrams, or grams) of the medication contained in a specific volume (milliliters or liters).

An example of a common prepackaged drug concentration is 50% dextrose, 25 g/50 mL.

Note that medications are contained in different volumes of solution. This is your **volume on hand**. *To administer a medication, you must know the weight of the medication that is present in 1 mL.* This will tell you the concentration of the medication that you have on hand. The formula for calculating this is as follows:

$$\frac{\text{Total weight of the medication} \div}{\text{Total volume in milliliters}} = \text{Weight per milliliter}$$

By using this formula and the examples of common prepackaged medications, you will calculate how much of the medication is contained in each milliliter (dose on hand). For example, if the drug order is for dextrose, 25 g/ 50 mL, you would calculate the concentration as follows:

$$\begin{aligned} 25 \text{ g (total weight)} \div 50 \text{ mL (total volume)} \\ = 0.5 \text{ g/mL} \end{aligned}$$

Volume to Be Administered

After you have determined the concentration of the medication present in each milliliter (dose on hand), you must calculate how much volume is needed to give the amount of the medication ordered (desired dose). Use the following formula to calculate the volume to be administered:

$$\text{Desired dose (mg)} \div \text{Concentration on hand (mg/mL)} = \text{Volume to be administered (mL)}$$

Notice that the desired dose is in milligrams and the concentration on hand is in milligrams per milliliter. There may be instances where the desired dose is in a different unit, such as grams or micrograms. Before using the above formula, the units in the desired dose must match the units in the top of the concentration-on-hand fraction. If they do not, you will need to do a quick calculation to convert the desired dose units to match the units in the top half of the concentration on hand.

On the basis of the preceding formula, you will be able to determine how much volume to give to achieve the required dose. Here is an example:

Example 1:

You are ordered to administer 12.5 g of dextrose to a hypoglycemic patient. You have a prefilled syringe containing 25 g of D₅₀ in 50 mL. How many milliliters of dextrose will you give?

Step 1: Determine the concentration/dose on hand (in g/mL).

$$25 \text{ g} \div 50 \text{ mL} = 0.5 \text{ g/mL (dose on hand)}$$

Step 2: Determine how much volume to administer.

$$12.5 \text{ g (desired dose)} \div 0.5 \text{ g/mL (dose on hand)} = 25 \text{ mL}$$

You will need to administer 25 mL, or half of the 50-mL syringe.

Example 2:

You are ordered to administer 70 mg of medication “Y” to a patient. The medication is prepared as follows: 100 mg in 5 mL of saline. How many milliliters must you give to achieve the ordered dose?

Step 1: Determine the concentration/dose on hand (in mg/mL).

$$100 \text{ mg} \div 5 \text{ mL} = 20 \text{ mg/mL (dose on hand)}$$

Step 2: Determine how much volume to administer.

$$70 \text{ mg (desired dose)} \div 20 \text{ mg/mL (dose on hand)} = 3.5 \text{ mL}$$

You will need to administer 3.5 mL of the medication.

Weight-Based Medication Doses

As previously discussed, some medication doses are based on the patient’s weight in kilograms. Determining the appropriate dose for the patient requires simply converting the patient’s weight in pounds to kilograms and then proceeding with the formula that was just discussed. Remember, 1 kg equals 2.2 lb. As an AEMT, medications that you may administer and whose orders may be weight-based include pediatric dosages for dextrose, epinephrine, and naloxone.

The following are some examples of how to calculate the appropriate medication dose based on the patient’s weight:

Example 1:

You are ordered to give 0.1 mg/kg of naloxone (Narcan) to your 40-lb pediatric patient. You have a prefilled syringe of the medication containing 100 mg in 10 mL. How many

milligrams will you give to this patient? How much volume will you give to achieve the required dose?

Step 1: Convert the patient’s weight in pounds to kilograms.

$$\text{Formula 1: } 40 \text{ lb} \div 2.2 = 18.18 \text{ kg (round to 18 kg)}$$

$$\text{Formula 2: } 40 \text{ lb} \div 2 = 20 - 10\% = 18 \text{ kg}$$

Step 2: Determine the desired dose.

$$0.1 \text{ mg/kg} \times 18 \text{ kg} = 1.8 \text{ mg (desired dose)}$$

Step 3: Determine the concentration/dose on hand (in mg/mL).

$$100 \text{ mg} \div 10 \text{ mL} = 10 \text{ mg/mL (dose on hand)}$$

Step 4: Determine how much volume to administer.

$$1.8 \text{ mg (desired dose)} \div 10 \text{ mg/mL (dose on hand)} = 0.18 \text{ mL (round to 0.2 mL)}$$

Example 2:

A 4-year-old boy in asystole requires 0.01 mg/kg of epinephrine. You have a prefilled syringe of epinephrine containing 1 mg in 10 mL. The child’s mother tells you that he weighs 35 lb. How many milligrams will you give to this patient (that is, what is the desired dose)? How much volume will you give to achieve the required dose?

Step 1: Convert the patient’s weight in pounds to kilograms.

$$\text{Formula 1: } 35 \text{ lb} \div 2.2 = 15.9 \text{ kg (round to 16 kg)}$$

$$\text{Formula 2: } 35 \text{ lb} \div 2 = 17.5 - 10\% = 15.75 \text{ kg (round to 16 kg)}$$

Step 2: Determine the desired dose.

$$0.01 \text{ mg} \times 16 \text{ kg} = 0.16 \text{ mg/kg (desired dose)}$$

Step 3: Determine the concentration/dose on hand (in mg/mL).

$$1 \text{ mg} \div 10 \text{ mL} = 0.1 \text{ mg/mL (dose on hand)}$$

Step 4: Determine how much volume to administer.

$$0.16 \text{ mg (desired dose)} \div 0.1 \text{ mg/mL (dose on hand)} = 1.6 \text{ mL (round to 2 mL)}$$

Special Populations

It is important to administer the most appropriate dose of a medication to a child. Many parents or caregivers know how much their children weigh in pounds, which you can easily convert to kilograms (1 kg = 2.2 lb). If a parent or caregiver is available, simply ask the child's weight; do not attempt to estimate the child's weight if it is not necessary.

Pediatric Doses

There are several methods for determining the appropriate dose of medication for a pediatric patient. Many rescuers use length-based resuscitation tapes; others may carry a field guide with tables or charts for reference. Most medications used in pediatric emergency medicine are based on the child's weight in kilograms. The calculations for pediatric drug dosing and medication infusions are the same as they are for adults, but the doses and volumes will be obviously smaller.

Steps for Administering by Specific Routes

Up to this point, this chapter has covered principles of medication administration, basic cell physiology, IV therapy, and mathematical principles. This last section will discuss steps for administering medications by the specific routes. Steps for administering medications for system-specific emergencies are given in later chapters; such instances are noted.

Administering Enteral Medications

Enteral medications are those that are given through some portion of the digestive or intestinal tract. This includes medications that are administered orally, through a feeding tube, or rectally.

Oral Administration

Forms of solid and liquid oral medications include capsules, timed-release capsules, lozenges, pills, tablets, elixirs, emulsions, suspensions, and syrups. Oral medications are used when the desired effect is systemic and the medications are taken up by the intestines. To give oral medications, you may use a small medicine cup, a medicine dropper, a teaspoon, an oral syringe, or a nipple. Gather the appropriate

equipment for the form of medication you are administering. As with any medication, check for indications, contraindications, precautions, and the rights before administering an oral medication. Medications administered by AEMTs using the oral route include aspirin and oral glucose.

Follow these steps when administering an oral medication (**FIGURE 13-42**):

1. Take standard precautions.
2. Determine the need for the medication based on patient presentation.
3. Obtain a history, including any medication allergies.

A

B

FIGURE 13-42 Administering an oral medication.

A. Check the rights of medication administration. **B.** Have the patient take the medication. Administer a cup of water if necessary.

4. Follow standing orders, or contact medical control for permission.
5. Check the medication to be sure it is the right medication and not cloudy or discolored and that its expiration date has not passed. Check the rights of medication administration.
6. Determine the appropriate dose. If the medication is liquid, pour the desired amount into a calibrated cup.
7. Instruct the patient to swallow the medication with water, if administering a pill or tablet.
8. Monitor the patient's condition, and document the medication given, route, time of administration, and patient response.

Safety

Standard precautions should be used any time you are administering a medication.

Rectal Administration

Some AEMTs may be allowed to administer D_{50} , but whether rectal administration is allowed depends on local protocols. If allowed, administering D_{50} by this route is a last resort, when a patient is hypoglycemic and no other route is an option (IV access cannot be established). Check for indications, contraindications, and precautions before giving D_{50} rectally (**FIGURE 13-43**).

Follow these steps to administer a medication rectally:

1. Take standard precautions.
2. Determine the need for the medication based on patient presentation.
3. Obtain a history, including any medication allergies.
4. Follow standing orders, or contact medical control for permission.
5. Determine the appropriate dose, and check that the medication is the right medication, there is no cloudiness or discoloration, and the expiration date has not passed.
6. When inserting a suppository, use a water-soluble gel for lubrication. Insert the suppository into the rectum approximately 1 to 1.5 inches (3 to 4 cm) while instructing the patient to relax and not to bear down.

FIGURE 13-43 The rectal mucosa is highly vascular and rapidly absorbs medications.

© Jones & Bartlett Learning.

7. For medications that are in liquid form, some modifications are needed. You may use a nasopharyngeal airway, a small endotracheal (ET) tube, an 18-gauge IV catheter without a needle, or a commercial device as your delivery device.
 - a. Lubricate the end of the nasal airway or ET tube with a water-soluble gel, and gently insert it approximately 1 to 1.5 inches (3 to 4 cm) into the rectum. Instruct the patient to relax and not to bear down.
 - b. With a *needleless* syringe, gently push the medication through the tube.
 - c. After the medication has been delivered, remove and dispose of the tube or syringe in an appropriate container.
8. Monitor the patient's condition, and document the medication given, route, time of administration, and patient response.

Administering Parenteral Medications

Parenteral medications are those that are given through any route other than the GI tract. Parenteral

routes used by the AEMT include subcutaneous, IM, IV bolus, IO, sublingual, transcutaneous, transdermal, and inhalation. Of the parenteral medication routes, IV administration is the most common route used in the prehospital setting and generally is the quickest route for getting medication into the central circulation.

Equipment

A variety of needles and syringes are used for administering parenteral medications. Most syringes come prepackaged in color-coded packs with a needle already attached. The needles and syringes may also be packaged separately. You must choose the appropriate-size syringe and appropriate needle length for the desired route. Syringes consist of a plunger, body or barrel, flange, and tip (**FIGURE 13-44**). Most syringes are marked with 10 calibrations per milliliter on one side of the barrel, where each small line represents 0.1 mL. The 3-mL syringe is the most commonly used for injections, but others are available as needed. Needle lengths vary from $\frac{3}{8}$ inch (1 cm) to 2 inches (5 cm) for standard injections.

Packaging

Parenteral medications are most commonly packaged in ampules, vials, and prefilled syringes. **Ampules** are breakable sterile glass containers that are designed to carry a single dose of medication (**FIGURE 13-45**). **Vials** may contain single or multiple doses (**FIGURE 13-46**). Vials have a rubber-stopper top and are made of glass or plastic. Many medications used in prehospital care are carried in vials. Prefilled syringes are designed for ease of use. It is much easier and quicker to use a prefilled

syringe when you are treating a patient in cardiac arrest than it is to draw up each individual dose. There are also single-dose disposable cartridges that use a reusable syringe such as a Tubex or Abboject (**FIGURE 13-47**). Some medications may need to be reconstituted, such as methylprednisolone sodium succinate (Solu-Medrol) and glucagon. These

FIGURE 13-45 Medication stored in ampules.

© Jones & Bartlett Learning.

FIGURE 13-44 A syringe consists of a plunger, body or barrel, flange, and tip.

FIGURE 13-46 Vials (single-dose and multidose).

© Jones & Bartlett Learning.

come with two vials, one with a powdered form of the medication and one with sterile water. **Drug reconstitution** involves injecting the sterile water from one vial into the vial that contains the powder, making a solution for injection.

Ampules

Naloxone (Narcan) is an example of a medication that comes in the form of an ampule. When drawing

FIGURE 13-47 A preassembled prefilled syringe.

© American Academy of Orthopaedic Surgeons.

Safety

Anytime you are using a needle to draw up medication or to inject blood into blood tubes, always hold the syringe against your palm with the needle pointing up and draw the vial or blood tube down onto the needle using the thumb and forefinger of the palm the syringe is braced against to avoid sticking yourself. This especially applies if you are in a moving ambulance.

a medication from an ampule, follow the steps in **SKILL DRILL 13-4**.

Vials

Epinephrine and naloxone (Narcan) are two examples of medications that may come in vials. When you are administering a vial of medication, you must first determine how much of the medication you will need and how many doses are in the vial.

Skill Drill 13-4 Drawing Medication From an Ampule

Step 1

Check the medication to be sure that the expiration date has not passed and that it is the correct medication and concentration.

Shake the medication down into the base of the ampule. If some of the medication appears to be stuck in the neck, gently thump or tap the stem.

Step 2

Using a 4 × 4-inch (10 × 10-cm) gauze pad or an alcohol prep, grip the neck of the ampule and snap it off where the ampule is scored. If the ampule is not scored and an attempt is made to break it, some sharp edges may be present. Drop the stem in the sharps container.

Step 3

Insert a filtered needle into the ampule without touching the outer sides of the ampule. Draw the solution into the syringe, and dispose of the ampule in the sharps container.

Skill Drill 13-4 Drawing Medication From an Ampule (*continued*)**Step 4**

Hold the syringe with the needle pointing up, and gently tap the barrel to loosen air trapped inside and cause it to rise.

**Step 5**

Press gently on the plunger to dispel any air bubbles. Recap the needle using the one-handed method to avoid contamination. Dispose of the needle in the sharps container and attach a standard hypodermic needle to the syringe, if necessary, to administer the medication.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

When drawing medication from a vial, follow the steps in **SKILL DRILL 13-5**.

For a single-dose vial, you will draw up the entire amount in the vial. For multiple-dose vials, you should draw out only the amount needed. Remember that after you remove the cover from a vial, it is no longer sterile. If you need a second dose, the top of the vial should be cleaned with alcohol before withdrawing the medication.

Some medications that are stored in vials need to be reconstituted; these may come in two separate vials or in a single vial divided into two compartments by a rubber stopper. An example of the latter is an Act-o-Vial (**FIGURE 13-48**). To reconstitute a medication contained in an Act-o-Vial, squeeze the two vials together, which releases the center stopper and allows the contents to mix. Shake vigorously to mix the contents before drawing out the medication.

To mix the contents of two separate vials, draw the fluid out of the first vial as described. Insert the syringe into the top of the second vial, and expel all fluid into it. Shake vigorously to mix. After the medication is reconstituted, regardless of the manner, draw up the medication as described for single- and multiple-dose vials.

Prefilled Syringe

Prefilled syringes come in tamper-proof boxes and are separated into the glass medication cartridge and a syringe (**FIGURE 13-49**). D₅₀W is an example of a medication that comes as a prefilled syringe.

To assemble the two-part prefilled syringe, pop the yellow caps off the syringe and the medication cartridge, insert the drug cartridge into the barrel of the syringe, and screw them together. Remove the needle cover, and expel air in the manner previously

Skill Drill 13-5 Drawing Medication From a Vial**Step 1**

Check the medication to be sure that the expiration date has not passed, and that it is the correct medication and concentration. Check that it is not discolored.

Remove the sterile cover, or clean the top with alcohol if it was previously opened.

**Step 2**

Determine the amount of medication that you will need, and draw that amount of air into the syringe. Allow a little extra room to expel some air while removing air bubbles.

**Step 3**

Invert the vial, clean the rubber stopper with an alcohol prep, and insert the needle through the rubber stopper into the medication. Expel the air in the syringe into the vial and then withdraw the amount of medication needed.

**Step 4**

After you have the correct amount of medication in the syringe, withdraw the needle and expel any air in the syringe.

**Step 5**

Recap the needle using the one-handed method and avoiding contamination. Label the syringe if it is not immediately given to the patient.

described. Follow the steps for the route the medication is to be given.

Subcutaneous Administration

Subcutaneous injections are given into the loose connective tissue between the dermis and the muscle layer (**FIGURE 13-50**). Volumes of a medication

administered subcutaneously are usually 1 mL or less. The injection is performed using a 24- to 26-gauge, 0.5- to 1-inch (1- to 3-cm) needle. Common sites include the upper part of the arms, anterior part of the thighs, and the abdomen (**FIGURE 13-51**). Patients who take insulin injections usually vary the sites owing to the multiple number of injections they require (usually daily). An example of an AEMT medication that is administered subcutaneously is epinephrine.

When you are preparing to administer fluid or medication, you will need to use aseptic technique, also called medical asepsis. This is a method of cleansing used to prevent contamination of a site when performing an invasive procedure such as starting an IV line or administering a medication. Aseptic technique may be accomplished via the sterilization of equipment used, antiseptics, or disinfectants.

FIGURE 13-48 An Act-o-Vial.

FIGURE 13-49 Prefilled syringes come in two parts, the glass medication cartridge and a syringe.

© Jones & Bartlett Learning.

FIGURE 13-50 A subcutaneous injection is below the dermis and above the muscle.

© Jones & Bartlett Learning.

FIGURE 13-51 Common sites for subcutaneous injections.

© Jones & Bartlett Learning.

Follow the steps in **SKILL DRILL 13-6** to administer a medication via the subcutaneous route.

IM Administration

Intramuscular (IM) injections are made by penetrating a needle through the dermis and subcutaneous tissue into the muscle layer (**FIGURE 13-52**). This allows administration of a larger volume of medication (up to 5 mL) than the subcutaneous route. Because there is also the potential for damage to nerves because of the depth of the injection, it is important to choose the appropriate site. Common anatomic sites for IM injections for adults and children include the following (**FIGURE 13-53**):

- **Deltoid muscle**—the muscle of the upper part of the arm that covers the prominence of the shoulder. The site for injection is approximately 1.5 to 2 inches (4 to 5 cm) below the acromion process on the lateral side.
- **Vastus lateralis muscle**—the large muscle on the lateral side of the thigh
- **Rectus femoris muscle**—the large muscle on the anterior side of the thigh
- **Gluteal area**—the buttocks, specifically the upper lateral aspect of either side

Skill Drill 13-6 Administering Medication via the Subcutaneous Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs. Follow standing orders, or contact medical control for permission. Check the medication to be sure that it is not cloudy, that the expiration date has not passed, and that it is the correct medication and concentration, and determine the appropriate dose.

Skill Drill 13-6 Administering Medication via the Subcutaneous Route (continued)

Step 2

Advise the patient of potential discomfort while explaining the procedure.

Assemble and check the equipment needed: alcohol preps and a 3-mL syringe with a 24- to 26-gauge needle. Draw up the correct dose of medication.

Step 3

Cleanse the area for the administration (usually the upper part of the arm or thigh) using aseptic technique.

Step 4

Pinch the skin surrounding the area, advise the patient of a stick, and insert the needle at a 45° angle.

Pull back on the plunger to aspirate for blood. The presence of blood in the syringe indicates you may have entered a vein. Remove the needle, and hold pressure over the site. Discard the syringe and needle in the sharps container. Prepare a new syringe and needle and select another site.

If there is no blood in the syringe, inject the medication and remove the needle. Immediately place it in the sharps container.

Step 5

To disperse the medication through the tissue, rub the area in a circular motion with your gloved hand. Properly store any unused medication. Monitor the patient's condition, and document the medication given, route, administration time, and patient response.

Words of Wisdom

When administering an IM medication, rub the area in a circular motion with your gloved hand to disperse the medication through the tissue.

FIGURE 13-52 An intramuscular injection is below the dermis and subcutaneous layer and into the muscle.

© Jones & Bartlett Learning.

AEMT medications that may be administered intramuscularly include epinephrine and glucagon. Follow the steps in **SKILL DRILL 13-7** to administer an IM injection.

Patients may also have their own auto-injector for certain medications such as epinephrine for anaphylactic reactions. Steps for administering specific injector devices are detailed in Chapter 22, *Immunologic Emergencies*.

Sublingual Administration

Sublingual and **buccal** medications enter the circulatory system much faster than those that travel through the enteral route. There is a vast network of vessels under the tongue (sublingual) and in the cheek (buccal). For a sublingual or buccal medication to work effectively, mucous membranes must be moist to allow the medication to dissolve. Medications given via the sublingual or buccal route may also be taken up in the proximal part of the GI tract without reaching the intestines.

Medications given by the sublingual route come in tablet, liquid, and spray forms. Nitroglycerin is a medication that is commonly given via the

FIGURE 13-53 Common sites for intramuscular injections. **A.** Deltoid muscles. **B.** Gluteal area. **C.** Vastus lateralis muscle. **D.** Rectus femoris muscle.

© Jones & Bartlett Learning.

Skill Drill 13-7 Administering Medication via the IM Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs. Follow standing orders, or contact medical control for permission.

Check the medication to be sure it is the correct one, that it is not discolored, and that the expiration date has not passed, and determine the appropriate dose.

Advise the patient of potential discomfort while explaining the procedure.

Assemble and check equipment needed: alcohol preps and a 3- to 5-mL syringe with a 21-gauge, 1- or 2-inch (4- or 5-cm) needle. Draw up the correct dose of medication and dispel air while maintaining sterility.

Step 2

Cleanse the area for the administration (usually the upper arm or the hip) using aseptic technique.

Step 3

Stretch the skin over the cleansed area, advise the patient of a stick, and insert the needle at a 90° angle.

Pull back on the plunger to aspirate for blood. The presence of blood in the syringe indicates you may have entered a blood vessel. Remove the needle and hold pressure over the site. Discard the syringe and needle in the sharps container. Prepare a new syringe and needle and select another site.

If there is no blood in the syringe, inject the medication and remove the needle.

Step 4

Cover the puncture site. Immediately dispose of the needle and syringe in the sharps container. Store any unused medication properly. Monitor the patient's condition, and document the medication given, route, administration time, and patient response.

Skill Drill 13-8 Administering Medication via the Sublingual Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs. Follow standing orders, or contact medical control for permission. Check the medication to make sure that it is the correct one and that its expiration date has not passed, and determine the appropriate dose.

© Jones & Bartlett Learning.

Step 2

Ask the patient to rinse their mouth with a little water if the mucous membranes are dry. Explain the procedure, and ask the patient to lift their tongue.

Place the tablet or spray the dose under the tongue, or ask the patient to do so. Advise the patient not to chew or swallow the tablet, but to let it dissolve slowly.

Monitor the patient's condition, and document the medication given, route, administration time, and patient response.

sublingual route, and it comes in tablet and spray forms. To administer a sublingual medication, follow the steps in **SKILL DRILL 13-8**.

Words of Wisdom

When you are administering or assisting with sublingual medications, have the patient rinse the mouth with a little water to help the medication dissolve if the mucous membranes are dry.

Oral glucose is an example of an AEMT medication administered via the buccal route. The technique for administering oral glucose is shown in Chapter 21, *Endocrine and Hematologic Emergencies*.

Intranasal Administration

Intranasal (within the nose) medications include nasal spray for congestion or solutions to moisten the nasal mucosa. In recent years, this route of medication administration has become increasingly more popular in the prehospital setting. Intranasally administered medications are rapidly absorbed, providing a more rapid onset of action than IM injections. Administration of emergency medications via the intranasal route is performed with a **mucosal atomizer device (FIGURE 13-54)**. The device attaches to a syringe and allows you to spray (atomize) select medications into the nasal mucosa.

Only a few emergency medications can be given intranasally, including naloxone (Narcan). Follow local protocol, or consult with medical control

FIGURE 13-54 Mucosal atomizer device.

Courtesy of LMA North America.

about the appropriate doses of these medications and any other medications that may be administered intranasally.

To administer a medication via the intranasal route, follow the steps in **SKILL DRILL 13-9**.

Medications Administered by the Inhalation Route

Many medications used in the treatment of respiratory emergencies are administered via the **inhalation** route. The most common inhaled medication is oxygen. Beta-2 agonist bronchodilators (eg, albuterol [Ventolin, Proventil], isoetharine [Bronkosol], metaproterenol [Alupent]) are often administered in the prehospital setting for patients experiencing respiratory distress caused by certain obstructive airway diseases, such as asthma, bronchitis, and emphysema. Other medications, such as ipratropium bromide (Atrovent)—an anticholinergic bronchodilator—are also administered via the inhalation route. Check your drug reference guide or the package insert for the indications, contraindications, and precautions before giving any of these medications.

Skill Drill 13-9 Administering Medication via the Intranasal Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs. Assemble and collect the needed equipment, including the mucosal atomizer device. Follow standing orders, or contact medical control for permission. Check the rights of medication administration out loud with your partner.

Step 2

Draw up the appropriate dose of medication in the syringe, dispel air, and reconfirm medication. Dispose of the needle properly.

(continues)

Skill Drill 13-9 Administering Medication via the Intranasal Route *(continued)*

Step 3

Attach the mucosal atomizer device to the syringe, maintaining sterility.

Step 4

Explain the procedure to the patient (or to a relative if the patient is unresponsive) and the need for the medication. Stop ventilation of the patient if necessary; remove any masks. Insert the mucosal atomizer device into the larger and less deviated or less obstructed nostril while pinching off the opposite nostril.

Quickly spray the medication dose into a nostril.

Step 5

Dispose of the atomizer device and syringe in the appropriate container.

Step 6

Monitor the patient's condition, and document the medication given, route, time of administration, and patient response.

FIGURE 13-55 Some medications are inhaled into the lungs with a metered-dose inhaler so that they can be absorbed quickly into the bloodstream.

© Jones & Bartlett Learning.

A patient with a history of respiratory problems will usually have a **metered-dose inhaler (MDI)** to use on a regular basis or as needed (**FIGURE 13-55**). MDIs are usually administered by the patient using the patient's own prescribed medications, but AEMTs must know how to administer via this route because they may assist the patient with administration. Medications administered by the MDI can be delivered through a mouthpiece held by the patient or by a mask, with or without a spacer device, for young children and patients who are unable to hold the mouthpiece (**FIGURE 13-56**).

Follow the steps in **SKILL DRILL 13-10** to help a patient self-administer medication from an inhaler.

Words of Wisdom

MDIs are also called HFAs, after the propellant hydrofluoroalkane that is now used instead of chlorofluorocarbons.

For more severe problems, liquid bronchodilators may be aerosolized in a **nebulizer** for inhalation. Small-volume nebulizers (also called updraft or handheld nebulizers) are the most commonly used method of administration of inhaled medications in the prehospital setting (**FIGURE 13-57**). Oxygen or a compressed air source is connected to the nebulizer to produce the aerosolized mist.

A

B

FIGURE 13-56 A. In children, a metered-dose inhaler and spacer can be used with or without a mask. **B.** Children as young as 6 months can use a mask and spacer device. A young child may be more cooperative if seated on a parent's lap.

© Jones & Bartlett Learning.

Some nebulizers have been adapted with child-friendly shapes and images to ease the use with pediatric patients. They may allow for blow-by administration to help the patient tolerate the medication. Other methods used on patients include a nebulized mask that does not require the patient to hold the device. Some adapters have been designed to allow providers to administer nebulized medications to intubated patients with each ventilation

Skill Drill 13-10 Assisting a Patient With a Metered-Dose Inhaler

Step 1

Take standard precautions. Obtain an order from medical control or follow local protocol. Assemble the needed equipment.

Ensure you have the right medication, right patient, right dose, and right route, and that the medication is not expired.

Ensure the patient is alert enough to use the inhaler. Check to see whether the patient has already taken any doses. Obtain baseline breath sounds for comparison after a few minutes of inhaler use. Ensure the inhaler is at room temperature or warmer.

Step 2

Shake the inhaler vigorously several times. Stop administering supplemental oxygen and remove any mask from the patient's face. Ask the patient to exhale deeply and, before inhaling, to put their lips around the opening of the inhaler.

Step 3

If the patient has a spacer, then attach it to allow more effective use of the medication. Have the patient depress the handheld inhaler and begin to inhale deeply.

Instruct the patient to hold their breath for as long they comfortably can to help the lungs absorb the medication.

Step 4

Continue administering supplemental oxygen.

Allow the patient to breathe a few times, then give the second dose per direction from medical control or according to local protocol. Monitor the patient's condition, and document the medication given, route, administration time, and response of the patient.

FIGURE 13-57 A small-volume nebulizer is used to deliver medications via aerosolized mist.

© Jones & Bartlett Learning.

FIGURE 13-58 A nebulizer can be attached to a bag-mask device and administered through the mask.

© Jones & Bartlett Learning.

(**FIGURE 13-58**). These devices may also be adapted for use with continuous positive airway pressure (CPAP) masks (**FIGURE 13-59**).

Follow the steps in **SKILL DRILL 13-11** to administer a medication via a small-volume nebulizer.

Some patients with respiratory emergencies may be breathing inadequately (ie, inadequate tidal volume, fast or slow respiratory rate) and will not be able to effectively inhale beta agonist medications into the lungs via a nebulizer or an MDI. In this case, use a small-volume nebulizer in-line with the assistive device. If the patient is intubated, then assist with bag-mask ventilation or a ventilator by placing a short piece of corrugated tubing,

FIGURE 13-59 A nebulized medication being administered through a continuous positive airway pressure mask.

© Pulmonary, Inc.

separated by a T piece, to connect the nebulizer. When utilizing CPAP, most manufacturers have a nebulizer that is designed to work with their device. The nebulizer should be placed between the assistive device and mask, or ET tube if the patient is intubated, with a separate oxygen line connected to the nebulizer.

IV Medication Administration

The IV route places the medication directly into the circulatory system. This is the fastest route of medication administration for AEMTs to administer because it bypasses most barriers to drug absorption. This also means that there is no room for error. Medications are administered by direct injection with a needle and syringe into an established peripheral IV line. Many services now use needleless systems to provide protection against needlesticks. In a needleless system, the syringe simply screws into the injection port.

As mentioned earlier, a bolus is a single dose given by the IV route. A bolus (in one mass) can be a small or large quantity of a drug. Some medications require an initial bolus and then a continuous IV infusion to maintain a therapeutic level of the medication. Recall that complications may arise from using the IV route, including the local and systemic complications discussed earlier in this chapter.

Skill Drill 13-11 Administering a Medication via a Small-Volume Nebulizer

Step 1

Take standard precautions. Determine the need for an inhaled bronchodilator based on patient presentation. Obtain a history, including any medication allergies and vital signs.

Follow standing orders, or contact medical control for permission. Check the rights of medication administration. Assemble and check needed equipment.

Step 2

If the medication is in a premixed package, then add it to the bowl of the nebulizer. If it is not premixed, then add the medication to the bowl and mix it with the specified amount of normal saline, usually 2.5 to 3 mL.

Step 3

Connect the T piece with the mouthpiece to the top of the bowl, or the mask to the bowl, and connect it to the oxygen tubing.

Set the flowmeter at 6 L/min to produce a steady mist. Remove the oxygen mask from the patient if oxygen is being administered.

Step 4

With the MDI or handheld nebulizer in position, instruct the patient on the proper way to breathe. Have the patient breathe as deeply as possible and hold their breath for 3 to 5 seconds before exhaling. Continue to coach the patient as needed.

Monitor the patient's condition, and document the medication given, route, time of administration, and response of the patient to the medication.

Follow the steps in **SKILL DRILL 13-12** when administering a medication via the IV bolus route.

Follow these steps to administer a medication through a saline lock, or intermittent site:

1. Take standard precautions.
2. Determine the need for the medication based on patient presentation.
3. Obtain a history, including any medication allergies and vital signs.
4. Follow standing orders, or contact medical control for permission.
5. Check the rights of medication administration including ensuring that it is not cloudy or discolored and that its expiration date has not passed.

Skill Drill 13-12 Administering Medication via the IV Bolus Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs.

Follow standing orders, or contact medical control for permission.

Check the medication to be sure that it is the correct one, that it is not cloudy or discolored, and that its expiration date has not passed, and determine the appropriate dose.

Explain the procedure to the patient and the need for the medication. Assemble needed equipment, and draw up the medication. Expel any air in the syringe. Draw up 20 mL of normal saline to use as a flush for the medication.

Cleanse the injection port with alcohol, or remove the protective cap if using the needleless system.

Step 2

Insert the needle into the port (or screw the syringe into the needleless hub) and pinch off the IV tubing proximal to the administration port. Failure to shut off the line will result in the medication taking the path of least resistance and flowing into the bag instead of into the patient.

Administer the correct dose of the medication at the appropriate rate. Some medications must be administered very quickly, whereas others must be pushed slowly to prevent adverse effects.

Step 3

Place the needle and syringe into the sharps container.

Unclamp the IV line to flush the medication into the vein. Allow it to run briefly wide open, or flush with a 20-mL bolus of normal saline.

Readjust the IV flow rate to the original setting.

Properly store any unused medication.

Monitor the patient's condition, and document the medication given, route, time of administration, and patient response.

6. Explain the procedure to the patient and the need for the medication.
7. Assemble needed equipment, and draw up the medication. Draw up 20 mL of normal saline to use as a flush for the medication.
8. Cleanse the injection port with alcohol, or remove the protective cap if using the needleless system.
9. Insert the needle into the port while holding it carefully, or screw the syringe onto the port.
10. Pull back slightly on the syringe plunger, and observe for blood return. If blood appears, slowly inject the medication, watching for infiltration. If resistance is felt, or if the patient complains of any discomfort, discontinue administration immediately. A new site will need to be established.
11. Place the needle and syringe into the sharps container.
12. Clean the port, and insert the needle with the syringe containing the flush.
13. Flush the saline lock, and place the needle in the sharps container.
14. Store any unused medication properly.

15. Monitor the patient's condition, and document the medication given, route, time of administration, and patient response.

IO Medication Administration

The IO route is used for critically ill or injured children and adults when IV access is difficult or impossible to obtain. Any fluid or medication that may be given through an IV line—bolus or maintenance infusion—can be given by the IO route. Shock, status epilepticus, and cardiac arrest are a few of the reasons for establishing IO access.

Unlike with an IV line, fluid does not flow well into the bone because of resistance; therefore, it is necessary to use a large syringe to infuse the fluid. A pressure infuser device—a sleeve placed around the IV bag and inflated to force fluid from the IV bag—should be used when infusing fluids in adults.

Complications of using the IO route are similar to those of the IV route. Along with the complications discussed earlier in this chapter, there is also the potential for compartment syndrome if fluid leaks outside the bone and into the osteofascial compartment.

Follow the steps in **SKILL DRILL 13-13** to administer a medication via the IO route.

Skill Drill 13-13 Administering Medication via the IO Route

Step 1

Take standard precautions. Determine the need for the medication based on patient presentation. Obtain a history, including any medication allergies and vital signs. Follow standing orders, or contact medical control for permission. Check the medication to ensure that it is the correct one, that it is not cloudy or discolored, and that the expiration date has not passed, and determine the appropriate amount and concentration for the correct dose.

Explain the procedure to the patient and/or parent and the need for the medication. Assemble needed equipment and draw up the medication. Also draw up 20 mL of normal saline for a flush.

Skill Drill 13-13 Administering Medication via the IO Route (continued)

Step 2

Cleanse the injection port of the extension tubing with alcohol, or remove the protective cap if using the needleless system.

Step 3

Insert the needle into the port, and clamp off the IV tubing proximal to the administration port. This is usually managed with a three-way stopcock. Failure to shut off the line will result in the medication taking the pathway of least resistance and flowing into the bag instead of into the patient. Administer the correct dose of the medication at the proper push rate. Some medications must be administered quickly, whereas others must be pushed slowly to prevent adverse effects.

Step 4

Place the needle and syringe into the sharps container. Unclamp the IV line to flush the medication into the site. Flush with at least a 20-mL bolus of normal saline. Readjust the IV flow rate to the original setting. Store any unused medication properly.

Monitor the patient's condition, and document the medication given, route, time of administration, and response of the patient.

YOU are the Provider SUMMARY

1. On the basis of the information given, do you think this patient will require IV access?

The patient's mechanism of injury and complaint of abdominal pain indicate that at least one IV line should be initiated, although two IV lines are preferred. Because this patient is reporting abdominal pain, it is important to have IV access in case she becomes hypotensive and requires fluid administration.

2. What is the appropriate-size IV catheter for this patient?

This patient requires fluid resuscitation. Previously, the largest IV catheter that you could successfully place would have been the correct answer. Because the goals of fluid resuscitation are to administer up to four boluses of 250 mL each followed by a reassessment of the blood pressure after each bolus, the catheter should be large enough to allow for rapid administration of the 250-mL bolus. Current recommendations in hemorrhagic shock are to use at least one 18-gauge angiocatheter. This decreases the risk of an unsuccessful cannulation attempt relative to use of a larger catheter. A second IV catheter of similar diameter or larger should be established during transportation. Remember that the more distal the IV site, the smaller the catheter. Metacarpal veins of the hand accommodate 18- to 20-gauge catheters with more difficulty than do more proximal veins. Antecubital veins of the upper part of the arm can accommodate larger catheters.

3. Does this patient require any medications, and, if so, by what route should they be administered?

Given the mechanism of action and your physical exam findings, this patient requires oxygen administration. It is important to remember that medical-grade oxygen is a medication and, as such, requires you to ascertain a thorough medical history prior to administration. Oxygen is given via the inhalation route, either through a mask, nasal cannula, or a nebulizer. In trauma patients, oxygen should always be given via a nonrebreathing mask.

4. What are the rights of medication administration?

Prior to administering any medication, you must ensure the rights of medication administration: right patient, right medication, right dose, right route, right time, right documentation and reporting, right assessment, right to refuse, right evaluation, and right patient education.

5. What type of fluid should you administer to this patient?

This patient should be given an isotonic solution such as 0.9% sodium chloride or lactated Ringer solution. Because normal saline has almost the same osmolarity as serum and other body fluids, it stays inside the intravascular compartment. Isotonic solutions expand the contents of the intravascular compartment without shifting fluid to or from other compartments. Awareness of this fact is useful when dealing with hypotensive or hypovolemic patients. Although isotonic fluid does a good job of hydrating, this fluid remains in the vascular compartment, so you must be careful to avoid fluid overloading.

6. How much fluid should be administered to this patient?

In trauma patients, AEMTs should administer up to four boluses of 250 mL each titrated to achieve a systolic blood pressure greater than 80 to 90 mm Hg with reassessment of the blood pressure and heart rate after each bolus. Check with medical control before administering more medication.

7. Why is it important to constantly reassess breath sounds when you are administering fluid to a patient?

An unmonitored IV bag can result in circulatory overload. Healthy adults can handle as much as 2 to 3 extra liters of fluid without compromise. Problems occur when the patient has cardiac, pulmonary, or renal dysfunction or has recently been experiencing active bleeding. These types of dysfunction do not tolerate any additional demands from increased circulatory volume. The most common cause of circulatory overload in the prehospital setting is failure to readjust the drip rate after flushing an IV line immediately after insertion. Always monitor IV bags to ensure the proper drip rate. Patient presentation of circulatory overload includes dyspnea, jugular venous distention, and increased blood pressure. Crackles (formerly known as rales) are often heard when evaluating breath sounds. Acute peripheral edema can also be an indication of circulatory overload. In the case of recent active bleeding, driving the blood pressure to or even above normal levels risks disrupting clots that may have formed and which have helped control hemorrhage. This clot disruption can exacerbate underlying bleeding.

YOU are the Provider SUMMARY *continued***8. What are some possible complications of vein cannulation?**

Peripheral IV insertion carries associated risks. The problems associated with IV lines can be categorized as either local or systemic reactions. Local reactions

include problems such as infiltration; thrombophlebitis; occlusion; vein irritation; hematoma; nerve, tendon, or ligament damage; and arterial puncture. Systemic complications include circulatory overload, air embolus, vasovagal reactions, and catheter shear.

EMS Patient Care Report (PCR)

Date: 10-1-20	Incident No.: 20100152	Nature of Call: MVC		Location: Main & 1st Street	
Dispatched: 1218	En Route: 1220	At Scene: 1225	Transport: 1234	At Hospital: 1256	In Service: 1324

Patient Information

Age: 35
Sex: F
Weight (in kg [lb]): 75 kg (165 lb)

Allergies: None
Medications: None
Past Medical History: None
Chief Complaint: Severe abdominal pain

Vital Signs

Time: 1230	BP: Not obtained	Pulse: Not obtained	Respirations: 20	Spo₂: Not obtained
Time: 1236	BP: 76/40	Pulse: 121	Respirations: 20	Spo₂: 100% on 15 L/min
Time: 1246	BP: 86/48	Pulse: 130	Respirations: 20	Spo₂: 100% on 15 L/min

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): NC (NRM) Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	Other:

Narrative

EMS dispatched to above location for reported MVC. On arrival find single-vehicle MVC, where sedan impacted telephone pole at approximately 45 miles per hour. Patient found seated in driver's seat, AO × 4, ABCs intact. Immediate manual stabilization performed, cervical collar applied, patient extricated to long backboard. Rapid assessment reveals severe pain and bruising to lower abdominal area, coupled with distention. Secured to stretcher, transport emergent to Charity hospital. En route – Vitals as above. Nonrebreathing mask at 15 L/min applied. Bilateral 18-gauge IVs established to AC, with initial 250-mL normal saline bolus administered because of patient's hypotension. Report called to online medical control with condition and ETA. At conclusion of fluid bolus, breath sounds clear bilaterally, patient remains hypotensive. 2nd 250-mL bolus given, with slight increase in blood pressure. On arrival, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- As an AEMT, it is your responsibility to thoroughly understand how medications affect the body.
- The danger of something going wrong when administering a medication—for example, administering the wrong medication or the wrong dose of a medication—can be minimized by confirming the rights of medication administration: right patient, right medication, right dose, right route, right time, right documentation and reporting, right assessment, right to refuse, right evaluation, and right patient education.
- Follow a set procedure when you administer any medication. A safe procedure begins with obtaining an order from medical control and making sure you understand the physician's orders. Repeat any orders word for word for verification.
- You must inquire about any medication allergies that the patient may have. Verify the proper medication and prescription. Verify the form, dose, and route of the medication.
- You must also check the expiration date and condition of the medication before its administration and confirm medication compatibility.
- The final steps of medication administration are to notify the physician when the medication has been administered, monitor the patient for effects, and advise medical control of any changes in the patient's condition. Document your actions and the patient's responses.
- Dispose of any syringes and needles safely in a sharps container, and do not recap needles.
- A certified AEMT is allowed to administer or help patients self-administer numerous medications: oxygen, oral glucose, glucagon, dextrose, epinephrine, MDI medications, nebulized medications, nitroglycerin, nitrous oxide, naloxone, aspirin, and possibly others based on local protocol.
- AEMTs may administer IV fluids, including D₅W, normal saline, and lactated Ringer solution.
- AEMTs may only administer medications and fluids when either directly ordered by medical control or allowed by local protocols or standing orders.
- An understanding of basic cell physiology can help an AEMT understand why different types of IV fluids are administered for different conditions. The cellular environment contains ions, or electrolytes, that are used by the cell for different purposes, depending on its needs. These ions include sodium, potassium, calcium, bicarbonate, chloride, and phosphorus. Their electrical charges must remain in balance on either side of the cell membrane.
- There must be a balance of compounds on either side of the cell membrane. If an imbalance occurs, the cell can move chemicals or charges across its membrane by various methods, including diffusion, filtration, active transport, and osmosis.
- Becoming familiar with the various types of IV solutions will give you an understanding of their use in relation to patient conditions. IV solutions are categorized by dissolved components (crystalloid and colloid) and by tonicity (isotonic, hypotonic, hypertonic).
- Crystalloid solutions are dissolved crystals in water and contain compounds that quickly disassociate in solution. These solutions are the best choice for the patients who need fluid replacement.
- Colloid solutions contain molecules that are too large to pass out of the capillary membranes and therefore remain in the vascular compartment. These are not generally used in the prehospital setting. Examples of colloids are albumin, dextran, and hetastarch.
- Isotonic solutions have nearly the same osmolarity as serum and other body fluids; therefore, these solutions stay inside the intravascular compartment. Hypotonic solutions have a lower concentration of sodium than the cell; these solutions pull fluid

from the vascular compartment into the interstitial fluid compartment. Hypertonic solutions have a higher osmolarity than serum and shift fluids into the intravascular compartment.

- Successful IV administration technique takes practice. Several factors, from the patient's condition to the available IV equipment, influence every IV start. Mastery of IV therapy skills comes when you understand and can overcome all the variables. Take your time when you practice inserting an IV line and gain a solid understanding of what you are doing. This understanding will be useful when you need to start a quick and flawless IV line in less than optimum conditions.
- During IV therapy, it is critical to always keep equipment sterile.
- You will need to choose an IV solution and administration set. There are different sizes of administration sets for different situations and patients. Administration sets come in two primary sizes: microdrip and macrodrip. Microdrip sets are ideal for medication administration; macrodrip sets are best for fluid replacement.
- Before administering IV fluid, you will need to choose an IV site, spike the bag, and choose a catheter. Catheters are sized by their diameter and referred to by the gauge of the catheter. The larger the diameter of the catheter, the smaller the gauge. The larger the diameter, the more fluid can be delivered through the catheter.
- After you have gained vascular access, you will need to secure the line and remove the constricting band.
- Possible complications of IV therapy include local reactions and systemic reactions.
- Infiltration is the escape of fluid into the surrounding tissue. This escape of fluid causes a localized area of edema. To correct the infiltration, discontinue administration and reestablish an IV line in the opposite extremity or at a more proximal location on the same extremity. Apply direct pressure over the swollen area to reduce further swelling or bleeding into the tissue.
- Occlusion is the physical blockage of a vein or catheter. If the flow rate is not sufficient to keep fluid moving out of the catheter tip and if blood enters the catheter, a clot may form and occlude the flow.
- A hematoma is an accumulation of blood in the tissues surrounding an IV site. Blood can be seen rapidly pooling around the IV site, resulting in tenderness and pain. If a hematoma develops while you are attempting to insert a catheter, stop and apply direct pressure to help minimize bleeding. If a hematoma develops after a successful catheter insertion, evaluate the IV flow and the hematoma.
- Any allergic reaction must be treated aggressively. Patient presentation depends on the extent of the reaction. If an allergic reaction occurs while administering medication through an IV, discontinue administration and remove the solution. Notify medical control immediately and maintain an open airway.
- Treat a patient with a suspected air embolus by placing the patient on the left side with the head down to trap any air inside the right atrium or right ventricle and rapidly transport to the closest most appropriate facility. Be prepared to assist ventilations if the patient experiences increasing shortness of breath or inadequate tidal volume. Document the event.
- Catheter shear occurs when part of the catheter is pinched against the needle, and the needle slices through the catheter, creating a free-floating segment. Treatment involves surgical removal of the sheared tip.
- An unmonitored IV bag can result in circulatory overload. Always monitor IV bags to ensure the proper drip rate. To treat a patient with circulatory overload, slow the IV rate to keep the vein open and raise the patient's head to ease respiratory distress. Administer high-flow oxygen and monitor vital signs and breathing adequacy. Contact medical control immediately and document the event.
- Administering IV therapy to pediatric and geriatric patients requires special care. Both populations are at a higher risk for certain medical conditions that can affect both the patient's need for IV therapy and the effectiveness of the

therapy. By understanding the risks and concerns of these populations, you will be better equipped to properly administer IV therapy. In any medical situation involving pediatric or geriatric patients, remember to be sensitive to the patient's personal issues.

- IO administration (administration of fluids or medications into the bone) is an alternative if IV access is difficult or impossible. Any fluid or medication that can be administered via the IV route can be administered via the IO route and can travel to the central circulation just as rapidly.
- Good math skills, along with an understanding of the metric system, are imperative to providing

the correct dose for the patient. Practice your math skills frequently to stay proficient.

- As an AEMT, you should be familiar with the various routes of medication administration. This includes an understanding of the proper use of equipment and proper anatomic locations for administration. Enteral administration includes the administration of all medications that may be given through any portion of the digestive tract. The parenteral route includes any method of medication administration that does not go through the digestive tract.
- When in doubt, always follow local protocols or contact medical control for direction.

Vital Vocabulary

access port A sealed hub on an administration set designed for sterile access to the intravenous fluid.

acidosis A pathologic condition that results from the accumulation of acids in the body; an increase in extracellular H^+ ions; a blood pH of less than 7.35.

active transport A method used to move compounds across a cell membrane to create or maintain an imbalance of charges.

administration set Tubing that connects to the intravenous bag access port and the catheter to deliver the intravenous fluid.

air embolus The presence of air in the veins, which can result in cardiac arrest if it enters the heart.

alkalosis A pathologic condition resulting from the accumulation of bases in the body; a decrease in extracellular H^+ ions; a blood pH greater than 7.45.

ampules Small glass containers that are sealed and the contents sterilized.

anion An ion that contains an overall negative charge.

antecubital The anterior aspect of the elbow.

aseptic technique A method of cleansing used to prevent contamination of a site when performing

an invasive procedure, such as inserting an intravenous line.

ataxia A staggered walk or gait caused by injury to the brain or spinal cord.

bolus A term used to describe “in one mass”; in medication administration, a single dose given by the intravenous route; may be a small or large quantity of the drug.

Bone Injection Gun (BIG) A spring-loaded device that is used for inserting an intraosseous needle into the proximal tibia in adult and pediatric patients.

buccal A medication route in which the medication is placed between the cheek and gums, where it is absorbed into the bloodstream.

buffer A substance or group of substances that controls the hydrogen levels in a solution.

butterfly catheters Rigid, hollow, venous cannulation devices identified by plastic “wings” that act as anchoring points for securing the catheter.

cannulation The insertion of a hollow tube into a vein to allow for fluid flow.

capillary beds The terminal ends of the vascular system where fluids, food, and wastes are exchanged between the vascular system and the cells of the body.

catheter A flexible, hollow structure that delivers fluid.

catheter shear A free-floating segment of a catheter in the circulatory system, created if the needle slices through the catheter while it is being inserted.

cation An ion that contains an overall positive charge.

cellular perfusion The ability of a cell to take in oxygen and remove carbon dioxide.

colloid solution A type of intravenous solution that contains compounds that are too large to pass out of the capillary membranes and therefore remain in the vascular compartment; for example, used to help reduce edema.

concentration The total weight of a drug contained in a specific volume of liquid.

concentration gradient The natural tendency for substances to flow from an area of higher concentration to an area of lower concentration, either within the cell or outside the cell.

contaminated stick The puncturing of an emergency care provider's skin with a catheter that was used on a patient.

crystalloid solution A type of intravenous solution that contains compounds that quickly dissociate in solution and can cross membranes; considered the best choice for prehospital care of injured patients who need fluids to replace lost body fluid.

D₅W An intravenous solution made up of 5% dextrose in water.

depolarization The rapid movement of electrolytes across a cell membrane that changes the cell's overall charge. This rapid shifting of electrolytes and cellular charges is the main catalyst for muscle contractions and neural transmissions.

desired dose The amount of a drug that the physician orders for a patient; the drug order.

diaphysis The shaft of a long bone.

diffusion The movement of solutes (molecules) from an area of higher solute concentration to an area of lower solute concentration.

drip chamber The area of the administration set where fluid accumulates so that the tubing remains filled with fluid.

drip rate Number of drops per minute.

drip set Another name for an administration set.

drug reconstitution Injecting sterile water (or saline) from one vial into another vial containing a powdered form of the drug.

electrolytes Charged atoms or compounds that result from the loss or gain of an electron. These are ions that the body uses to perform certain critical metabolic processes.

enteral medications Medications that are given through a portion of the gastrointestinal tract.

epiphyseal plate The growth plate of the bone; responsible for normal bone growth and development during childhood.

epiphyses The articular end of a long bone; also called the epiphyseal plates.

external jugular IV lines Intravenous catheters established in the jugular veins of the neck.

EZ-IO A handheld, battery-powered driver to which a special intraosseous needle is attached; used for insertion of the intraosseous needle into the proximal tibia of children and adults.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

FAST devices Manual sternal intraosseous devices used in patients age 12 years and older; include an infusion tube, subcutaneous portal, an introducer, a target/strain relief patch, and a protective dome.

filtration A type of diffusion in which water carries dissolved compounds across the cell membrane; commonly used by the kidneys to clean blood.

flash chamber The area of a catheter that fills with blood to help indicate when a vein is cannulated.

gauge In the medication administration sense, the interior diameter of a catheter or needle.

gtt A measurement that indicates drops.

hematoma An accumulation of blood in the tissues or in a body cavity.

homeostasis A tendency to constancy or stability in the body's internal environment; the balance of all systems of the body.

hypercalcemia An elevated blood calcium level.

hyperkalemia An elevated serum potassium level.

hypertonic solution A solution that has a greater concentration of sodium than does the cell; the increased extracellular osmotic pressure can draw water out of the cell and cause it to collapse.

hypocalcemia A decreased serum calcium level.

hypokalemia A decreased serum potassium level.

hypotonic solution A solution that has a lower concentration of sodium than the cell does; the increased intracellular osmotic pressure lets water flow into the cell, causing it to swell and possibly burst.

infiltration The escape of fluid into the surrounding tissue.

inhalation The active, muscular part of breathing that draws air into the airway and lungs; a medication delivery route; in allergic reactions, breathing in foreign substances through the respiratory system.

interstitial Water between the vascular system and the surrounding cells (for example, between the membranes of two cells located outside the vascular compartment in the body).

intramuscular (IM) Into a muscle; a medication delivery route.

intranasal A delivery route in which a medication is pushed through a specialized atomizer device, called a mucosal atomizer device, into the naris.

intraosseous (IO) Injection into the bone; a medication delivery route.

intraosseous space The spongy cancellous bone of the epiphyses and the medullary cavity of the diaphysis, collectively.

intravascular The water portion of the circulatory system surrounding the blood cells (for example, in the heart, arteries, or veins).

intravenous (IV) Injection into a vein; a medication delivery route.

ions Charged atoms or compounds that result from the loss or gain of an electron.

ionic concentration The amount of charged particles found in a particular area.

isotonic solution A solution that has the same concentration of solutes as does the cell. In this case, water does not shift, and no change in cell shape occurs.

lactated Ringer solution A sterile crystalloid isotonic intravenous solution of specified amounts of calcium chloride, potassium chloride, sodium chloride, and sodium lactate in water.

local reaction A mild or moderate allergic reaction that the body limits to a specific area after being exposed to a foreign substance.

lysis The process of disintegration, breakdown, or rupturing of cells caused by either the presence of certain enzymes, or from excess water entering the cell through osmosis.

macro drip set An administration set named for the large orifice between the piercing spike and the drip chamber; allows for rapid fluid flow into the vascular system.

metabolic Relating to the breakdown of ingested foodstuffs into smaller and smaller molecules and atoms that are used as energy sources for cellular function.

metered-dose inhaler (MDI) A miniature spray canister used to direct medications through the mouth to be inhaled into the lungs.

metric system A decimal system based on 10s for the measurement of length, weight, and volume.

micro drip set An administration set named for the small orifice between the piercing spike and the drip chamber; allows for carefully controlled fluid flow and is ideally suited for medication administration.

mucosal atomizer device A device that attaches to the end of a syringe that is used to spray (atomize) certain medications via the intranasal route.

nebulizer A device for producing a fine spray or mist that is used to deliver inhaled medications.

New Intraosseous (NIO) device A spring-loaded device that contains neither drill nor battery, used for inserting an intraosseous needle into the proximal tibia of an adult patient.

normal saline 0.9% sodium chloride; an isotonic crystalloid.

occlusion Blockage, usually of a tubular structure such as a blood vessel.

orthostatic hypotension Symptomatic drop in blood pressure related to the patient's body position, detected by measuring pulse and blood pressure while the patient is lying supine, sitting up, and standing. An increase in pulse rate and a decrease in blood pressure in any one of these positions is considered a positive sign for this condition.

osmolarity The ability to influence the movement of water across a semipermeable membrane.

osmosis The movement of a solvent (fluid), such as water, from an area of lower solute concentration to one of higher solute concentration through a selectively permeable membrane to equalize concentrations of a solute on both sides of the membrane.

osmotic pressure Pressure created against the cell wall by the presence of water.

osteogenesis imperfecta A congenital bone disease that results in fragile bones.

osteomyelitis Inflammation of the bone and muscle caused by infection; a potential complication of intraosseous infusion.

over-the-needle catheters The prehospital standard for intravenous cannulation, these consist of a hollow tube over a laser-sharpened steel needle; also referred to as an angiocath.

parenteral medications Medications that are given through any route other than through the gastrointestinal tract.

Penrose drain A type of surgical drain; can be used as a constricting band.

pH The measure of acidity or alkalinity of a solution.

phospholipid bilayer The cell membrane's double layer, consisting of a hydrophilic outer layer

composed of phosphate groups, and a hydrophobic inner layer made up of lipids, or fatty acids. It is this structure and composition that allows the cell membrane to have selective permeability.

piercing spike The hard, sharpened plastic spike on the end of the administration set designed to pierce the sterile membrane of the intravenous bag.

polyuria The passage of an unusually large volume of urine in a given period; in diabetes, this can result from wasting of glucose in the urine.

pressure infuser device A sleeve that is placed around the IV bag and inflated to force fluid to flow from the IV bag and into the tubing.

pulmonary embolus A blood clot trapped within the pulmonary circulation.

saline lock A type of intravenous (IV) access device that allows an active IV site to be maintained without having to run fluids through the vein, also called a buff cap or intermittent site.

sclerosis The hardening of tissue.

selective permeability The ability of the cell membrane to selectively allow compounds into the cell based on the cell's current needs.

sodium/potassium (Na^+/K^+) pump The mechanism by which the cell brings in two potassium (K^+) ions and releases three sodium (Na^+) ions.

subcutaneous Into the tissue between the skin and muscle; a medication delivery route.

sublingual Administration under the tongue; a medication delivery route.

syncopal episode Fainting; brief loss of consciousness caused by transiently inadequate blood flow to the brain.

systemic complications Moderate to severe allergic reactions affecting the systems of the body.

tachycardia A rapid heart rate of more than 100 beats per minute.

third spacing The shifting of fluid into the tissues, creating edema.

thrombophlebitis Inflammation of a vein.

tonicity The osmotic pressure of a solution, based on the relationship between sodium and water inside and outside the cell, that takes

advantage of chemical and osmotic properties to move water to areas of higher sodium concentration.

trocar A solid boring needle.

varicose veins Veins on the leg that are large, twisted, and ropelike and can cause pain, swelling, or itching.

vasovagal reaction A reaction consisting of precordial distress, anxiety, nausea, and sometimes syncope.

venous thrombosis The development of a stationary blood clot in the venous circulation.

vials Small glass bottles for medications; may contain single or multiple doses.

volume on hand The amount of fluid you have on hand, such as the amount of fluid in an intravenous bag or the amount of fluid in a vial of medication.

Chapter 14

Shock

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Shock and Resuscitation

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for a patient in shock, respiratory failure or arrest, cardiac failure or arrest, and postresuscitation management.

Pathophysiology

Applies comprehensive knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

KNOWLEDGE OBJECTIVES

1. Describe the physiology of perfusion, including the role of the autonomic nervous system in controlling blood pressure. (pp 767–768)
2. Discuss cardiac output, heart rate, stroke volume, and systemic vascular resistance. (p 768)
3. Discuss myocardial contractility, afterload, and preload, and how they relate to shock. (p 768)
4. Discuss the pathophysiology of shock (hypoperfusion). (pp 770–772)
5. Describe how the body compensates for decreased perfusion. (pp 772–774)
6. Explain how the body progresses to multiple-organ dysfunction syndrome (MODS). (p 776)
7. Recognize the causes of shock. (p 777)
8. Describe the various types of shock, including hypovolemic shock, cardiogenic shock, obstructive shock, and distributive shock. (pp 777–783)
9. Describe the signs and symptoms of shock. (pp 783–784)
10. Describe the three stages of shock. (p 785)
11. Explain the progression of shock, including the three distinct phases. (pp 785–787)
12. Discuss the assessment of a patient who could be in shock. (pp 787–789)
13. Describe the steps to follow in the emergency care of the patient with signs and symptoms of shock. (pp 790–793)
14. Discuss the role of fluid administration in treating a patient in potential shock. (p 793)
15. Discuss special considerations in fluid resuscitation. (pp 793–794)

SKILLS OBJECTIVES

1. Demonstrate how to complete an emergency medical services patient care report for a patient with bleeding and/or shock. (p 798)
2. Demonstrate how to treat a patient in potential shock. (p 792)

Introduction

Shock has several meanings. In this chapter, shock (hypoperfusion) describes a state of collapse and failure of the cardiovascular system. When the circulation of blood in the body becomes inadequate, the oxygen and nutrient needs of the cells cannot be met. In the early stages of shock, the body will attempt to maintain **homeostasis** (a balance of all systems of the body); however, as shock progresses, blood circulation slows and eventually ceases. This abnormal state of inadequate oxygen and nutrient delivery to the cells of the body causes organs and then organ systems to fail. If not treated promptly, shock can be fatal.

Shock can occur because of medical or traumatic events such as a heart attack, severe allergic reaction, internal or external bleeding from injuries sustained as a result of an automobile crash, or as a result of a gunshot wound. As an advanced emergency medical technician (AEMT), you will respond to these different types of emergencies to provide care and transportation for these patients. Therefore, you must be constantly alert to the signs and symptoms of shock. Maintain a high index of suspicion. The goal is to recognize shock in its early stages and provide appropriate treatment.

This chapter begins with a close-up look at **perfusion**, the function that fails in shock. Next, it looks at the physiologic causes of shock and describes each of its major forms. Finally, it discusses the assessment and emergency treatment of shock in general and of each kind of shock in particular. See Chapter 15, *BLS Resuscitation*, for resuscitation techniques.

Physiology of Perfusion

Perfusion is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal.

Perfusion requires having a working cardiovascular system. It also requires adequate gas exchange in the lungs, adequate nutrients in the form of glucose in the blood, and adequate waste removal, primarily through the lungs.

The body is perfused via the circulatory system. The circulatory system is a complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins. There are two circuits in the body: the systemic circulation in the body and the pulmonary circulation in the lungs. The systemic circulation, the circuit in the body, carries oxygen-rich blood from the left ventricle through the body and back to the right atrium. In the systemic circulation, as blood passes through the tissues and organs, it gives up oxygen and nutrients and absorbs cellular wastes and carbon dioxide. Carbon dioxide is one of the primary waste products of cellular work (metabolism) in the body and is removed from the body by the lungs. This is the reason why one of your primary concerns for your patient should be ensuring adequate ventilation and oxygenation.

Words of Wisdom

The following elements are collectively known as the **Fick principle**, which states that the movement and use of oxygen in the body depend on:

1. Adequate concentration of inspired oxygen (FiO_2 [fraction of inspired oxygen])
2. Appropriate movement of oxygen across the alveolar-capillary membrane into the arterial bloodstream
3. Adequate number of red blood cells (RBCs) to carry the oxygen
4. Proper tissue perfusion
5. Efficient off-loading of oxygen at the tissue level

YOU are the Provider

Part 1

Your ambulance is dispatched to a local residence to evaluate an elderly male patient reporting weakness and nausea. You find the patient lying supine in bed holding his hand over his abdomen. He states that he has not felt well over the past couple of days and feels as if he could pass out. He is pale, cool, and clammy.

1. What is shock and how does it relate to perfusion?
2. What factors does perfusion depend on?

Cardiac Output

Cardiac output is the volume of blood that the heart can pump per minute, and it depends on several factors. First, the heart must have adequate strength, which is largely determined by the heart muscle's ability to contract. This ability to contract is referred to as **myocardial contractility**. Second, the heart must receive adequate blood to pump. As the volume of blood coming to the heart increases, the heart's precontraction pressure in the heart builds up. This precontraction pressure is known as **preload**. As preload increases, the volume of blood within the ventricles increases, which causes the heart muscle to stretch. When the heart muscle is stretched, the strength of its contractions increases, resulting in increased cardiac output. Last, the resistance to flow in the peripheral circulation must be appropriate. The force or resistance against which the heart pumps is known as **afterload**.

Blood pressure, the pressure that is generated by the contractions of the heart and the dilation and constriction of the blood vessels, is usually carefully controlled by the body so that there is always sufficient circulation in the various tissues and organs, and it is a rough measure of perfusion. Because the heart cannot pump out what is not in its holding chambers, blood pressure varies directly with cardiac output, **systemic vascular resistance (SVR)**, and blood volume. (SVR is the resistance to blood flow within all blood vessels except the pulmonary vessels.) Remember that blood pressure is the pressure of blood within the vessels at any one time. The systolic pressure is the peak arterial pressure, or pressure generated every time the heart contracts; the diastolic pressure is the pressure maintained within the arteries while the heart rests between heartbeats.

Perfusion depends on cardiac output, SVR, and transport of oxygen.

Cardiac output = Heart rate $\times$ Stroke volume

Blood pressure = Cardiac output $\times$ Systemic vascular resistance

Mean arterial pressure (MAP) is generally considered to be the patient's blood pressure. However, MAP is ultimately the blood pressure required to sustain organ perfusion and is roughly 60 mm Hg in the typical resting adult. If the MAP falls

substantially below 60 mm Hg for an extended time, organ ischemia will result from lack of perfusion. MAP is approximated using this formula:

$$\text{MAP} \approx \text{Diastolic blood pressure} + \frac{1}{3} \text{ Pulse pressure (Systolic blood pressure} - \text{Diastolic blood pressure)}$$

Note this equation approximates MAP, as designated by the $\approx$ symbol.

The Role of the Nervous System

Control of the cardiovascular system is a function of the **autonomic nervous system**, which is composed of competing subsystems (**TABLE 14-1**). One of the subsystems, the sympathetic nervous system, which is sometimes known as the fight-or-flight system, prepares the body for physical activity during a stressful situation. This preparation includes increasing the pulse rate, blood pressure, and respiratory rate while dilating blood vessels in areas required for physical activity and constricting those in areas primarily involved with reproduction and restoration.

The autonomic nervous system is primarily regulated from the upper part of the medulla oblongata of the brain. Nerve signals caused by stimulation of the sympathetic nervous system travel between the brain and the body via nerves through the spinal cord. These nerves leave the spinal cord between each pair of vertebrae and spread out to affect the tissues in those areas (**FIGURE 14-1**). Another mechanism used by the sympathetic nervous system is the chemical release of epinephrine and norepinephrine from the adrenal glands into the bloodstream. These chemicals travel through the bloodstream to all parts of the body to activate a sympathetic response in those areas.

The other subsystem of the autonomic nervous system is the parasympathetic nervous system, which is primarily responsible for rest and regeneration (**FIGURE 14-2**). The parasympathetic nervous system opposes every action of the sympathetic nervous system. Where the sympathetic system increases the pulse rate, blood pressure, and respiratory rate, the parasympathetic system decreases these. The parasympathetic system also constricts blood vessels in muscular tissue and dilates those in the digestive system.

TABLE 14-1 Comparison of Sympathetic and Parasympathetic Nervous Systems

Features	Parasympathetic	Sympathetic
Other name for system	Cholinergic, rest and digest	Adrenergic, fight or flight
Natural chemical mediator	Acetylcholine	Norepinephrine, epinephrine
Primary nerve(s)	Vagus	Nerves from the thoracic and lumbar ganglia of the spinal cord
Effect of stimulation	Decreases cardiac contractility (negative inotropic effect) Slows conduction velocity (negative dromotropic effect) Slows the heart ^a (negative chronotropic effect) Constricts pupils Increases gut motility Increases salivation	Increases cardiac contractility (positive inotropic effect) Speeds conduction velocity (positive dromotropic effect) Speeds the heart ^a (positive chronotropic effect) Dilates pupils Slows the gut Dilates the bronchi

^aSlowing or speeding occurs mostly in the atria.

Regulation of Blood Flow

Blood flow through the capillary beds is regulated by the capillary **sphincters**, circular muscular walls that constrict and dilate, acting as a gate to increase or decrease flow. These sphincters are under the control of the autonomic nervous system. Capillary sphincters also respond to other stimuli such

as heat, cold, the need for oxygen, and the need for waste removal. Under normal circumstances, not all cells have the same needs at the same time. For example, the stomach and intestines have a high need for blood flow during and shortly after eating, when digestion is at a peak. Between meals, blood flow is lessened, and blood is diverted to other areas. The

brain, by contrast, needs a constant and consistent supply of blood to function.

Regulation of blood flow is determined by cellular need and is accomplished by vessel constriction or dilation, together with sphincter constriction or dilation. Maintenance of blood flow, or perfusion, is accomplished by the heart, blood vessels, and blood working together.

Respiration and Oxygenation

Each time you take a breath, the alveoli (microscopic, thin-walled air sacs) receive a supply of oxygen-rich air. The oxygen then dissolves in the blood plasma and attaches to the blood's hemoglobin. The oxygenated blood passes through the alveolar wall into the walls of a fine network of pulmonary capillaries that are in close contact with the alveoli. If the oxygenated blood is not properly circulated, some of the cells and organs will not receive proper nutrients, possibly resulting in cellular death.

Oxygen and carbon dioxide pass rapidly across these thin tissue layers through diffusion. Diffusion is a passive process in which molecules move from an area with a higher concentration of molecules to an area of lower concentration. There are more oxygen molecules in the alveoli than in the blood; therefore, the oxygen molecules move from the alveoli into the blood. Because there are more carbon dioxide molecules in the blood than in the inhaled air, carbon dioxide moves from the blood into the alveoli. Diffusion is discussed in more detail in Chapter 7, *The Human Body*.

Just like oxygen, a large portion of carbon dioxide is bound to the hemoglobin while the remainder is dissolved in the plasma, some of which combines with water to form carbonic acid. Carbonic acid concentrations become high just as the blood is moving toward the lungs. After it reaches the lungs, the carbonic acid breaks down and the carbon dioxide is exhaled. This action takes place to maintain the delicate balance between the gases and maintain the pH of the body.

Pathophysiology

Shock can result from inadequate cardiac output, decreased SVR, or the inability of RBCs to deliver oxygen to tissues. If there is a disturbance in the transportation of oxygen and removal of carbon dioxide, dangerous waste products will build up, resulting in cellular death and eventually death of

the entire organ. If the shock state persists, it will ultimately result in death of the entire organism (the body). As mentioned, shock, or hypoperfusion, is a state of collapse and failure of the cardiovascular system that results in inadequate circulation. To protect vital organs, the body attempts to compensate by shunting (directing) blood flow from organs that are more tolerant of low flow (such as the skin and intestines) to vital organs that cannot tolerate hypoperfusion (such as the heart, brain, and lungs). If the cause of shock is not promptly addressed, the patient will soon die.

The cardiovascular system consists of three parts: a pump (the heart), a set of pipes (the blood vessels or arteries that act as the container), and the contents of the container (the fluid or blood) (**FIGURE 14-3**). These three parts can be referred to as the perfusion triangle (**FIGURE 14-4**). When a patient is in shock, one or more of the three parts is not working properly.

Blood is the vehicle for carrying oxygen and nutrients through the vessels to the capillary beds to tissue cells, where these supplies are exchanged for waste products created during metabolism. For this process to happen, the vessels (container) must be intact. Blood contains RBCs, white blood cells, platelets, and plasma (the liquid portion of the blood). Hemoglobin (the protein inside RBCs) is responsible for the transportation of oxygen to the cells and for transporting carbon dioxide (a waste product of cellular metabolism) away from the cells to the lungs, where it is exhaled and removed from the body. White blood cells help the body to fight infection. Platelets are responsible for forming blood clots. Blood and its components are discussed further in Chapter 7, *The Human Body*.

Blood clots are an important response from the body to control blood loss. In the body, a blood clot forms depending on one of the following principles: retention of blood because of blockage in blood circulation (blood stasis), changes in the vessel wall (such as a wound), and the blood's ability to clot (as the result of a disease process or medication). When injury occurs to tissues in the body, platelets begin to aggregate at the site of injury; this causes the RBCs to become sticky and clump together. As the RBCs begin to clump, another substance in the body called fibrinogen reinforces the RBCs. This is the final step in the formation of a blood clot. Clots can become unstable and susceptible to rupture because blood is continually moving as a result of

FIGURE 14-3 The cardiovascular system consists of three parts: the pump (heart), the container (vessels), and the contents (blood). The blood carries oxygen (O₂) and nutrients through the vessels to the capillary beds, where they are exchanged for waste products (such as carbon dioxide [CO₂]).

© Jones & Bartlett Learning.

the blood pressure. The result may be an embolus at a distant site if the clot is venous or rebleeding if the clot is arterial.

The body's neural and hormonal mechanisms, including the autonomic nervous system and hormones, are triggered when the body senses that the pressure in the system is falling and the need for perfusion of vital organs is increased. The sympathetic side of the autonomic nervous system, which is responsible for the fight-or-flight response, will assume more control of the body's functions during a state of shock. The parasympathetic nervous system is a division of the autonomic nervous system that controls involuntary functions by sending signals to the cardiac, smooth, and glandular muscles and takes over during nonstressful situations. The sympathetic division of the autonomic nervous system causes the release of hormones such as epinephrine and norepinephrine. These hormones cause changes in certain body functions such as an increase in the heart rate and in the strength of

cardiac contractions and vasoconstriction in non-essential areas, primarily in the skin, muscles, and gastrointestinal tract (peripheral vasoconstriction). Together, these actions are designed to maintain pressure in the system and, as a result, sustain perfusion of the vital organs (ie, brain, heart, lungs, kidneys, and liver).

Eventually, there is also a shifting of body fluids to help maintain pressure within the system. However, the response of the autonomic nervous system and hormones comes within seconds. It is this response that causes all the signs and symptoms of shock in a patient.

Words of Wisdom

The Frank-Starling mechanism states that the length of the muscle fibers of the heart's wall determines the force of the contraction.¹ In other words, an increase in diastolic filling increases the force of the contraction, and a decrease in diastolic filling decreases the force of the contraction. Decreased perfusion in shock is the result of a decrease in cardiac contraction, which may be the result of loss of fluid, increased container size, or a damaged pump.

Compensation for Decreased Perfusion

Central among the homeostatic mechanisms that regulate cardiovascular dynamics are those that maintain blood pressure. When any event results in decreased perfusion (such as in blood loss, myocardial infarction, loss of vasomotor tone, or **tension pneumothorax**), the body must respond immediately to preserve the vital organs. **Baroreceptors** located in the aortic arch and carotid sinuses (as well as in most of the large arteries of the neck and thorax) sense the decreased blood pressure and flow and activate the vasomotor center in the medulla oblongata, which oversees changes in the diameter of blood vessels, to begin constriction of the vessels, therefore increasing blood pressure. Along with baroreceptors are **chemoreceptors**, which measure subtle shifts in the amounts of carbon dioxide in the arterial blood. In Chapter 7, *The Human Body*, you learned that these shifts have an effect on the regulation of the respiratory rate as well as control of the acid-base balance in the body.

Normally, stimulation occurs when the systolic pressure is between 60 and 80 mm Hg in adults or even lower in children. A decrease in the systolic pressure to less than 80 mm Hg stimulates the vasomotor center to increase the arterial pressure by constricting vessels. As the arterial pressure decreases, the walls of the arteries are not stretched as much, thereby decreasing baroreceptor stimulation. Normally, baroreceptor stimulation prevents the vasoconstrictor center of the medulla from constricting the vessels, resulting in vasodilation in the peripheral circulatory system and a decrease in pulse rate and contractility, causing a concomitant decrease in arterial pressure. With decreasing pressure, the baroreceptors are not stimulated to allow for vasodilation, so the vessels constrict to raise the blood pressure. The sympathetic nervous system is also stimulated as the body recognizes a potential catastrophic event. This message is sent to the adrenal glands to release epinephrine and norepinephrine into the bloodstream. These two naturally occurring “medications” will cause tachycardia and increase the contractility of the heart. Additionally, they will cause venous and arteriolar constriction, resulting in a decrease in blood flow to the skin, muscles, the gastrointestinal tract, and often the kidneys. This allows for a relative redistribution of blood to the brain and heart. Capillary hydrostatic pressure decreases in the compensated phase of shock, allowing fluid from the interstitial compartment to flow into the vessels.

Also, in response to hypoperfusion, the renin-angiotensin-aldosterone system in the kidneys is activated and antidiuretic hormone is released from the pituitary gland. Together, these mechanisms trigger salt and water retention and peripheral vasoconstriction. The result is an increase in the patient's blood pressure and maintenance of cardiac output. Depending on the severity of the insult, variable amounts of fluid will shift from the interstitial tissues into the vascular compartment. The spleen also releases some RBCs that are normally sequestered there to augment the blood's oxygen-carrying capacity. The overall response of the initial compensatory mechanisms is to increase the preload, stroke volume, and pulse rate, which usually results in an increase in cardiac output. This “autotransfusion” effect, along with the subtle effects in other response systems of the body (i.e., osmosis; insulin and glucagon production in the pancreas; as well

as the effects of the hormones arginine vasopressin [also known as antidiuretic hormone (ADH)], the adrenocorticotrophic hormone cortisol system, and somatotropin), allows the body to compensate adequately for a volume loss of up to 25%. Remember that shock is a *normal compensatory response* of the body, and disease can occur or become exacerbated when normal response systems are activated under abnormal conditions.

As hypoperfusion persists, the myocardial oxygen demand exceeds its supply. Eventually, the accelerated compensatory mechanisms are no longer able to keep up with the body's demand. Myocardial function then worsens, with decreased cardiac output and ejection fraction. Tissue perfusion decreases, resulting in impaired cell metabolism. Often, the systolic blood pressure decreases, especially in progressive hypoperfusion or “decompensated” shock. Fluid may leak from the blood vessels, as in the case of a severe allergic reaction, causing systemic and pulmonary edema.

As the patient decompensates, perfusion to the brain and coronary arteries decreases. Cells switch from aerobic to anaerobic metabolism. In **anaerobic metabolism**, cellular processes occur in the absence of oxygen; in contrast, in **aerobic metabolism** all cell processes occur with an adequate oxygen supply. This switch is a critical point, and lactic acidosis begins to develop from this inefficient form of metabolism. This also decreases cardiac function and makes the heart more susceptible to the effect of the circulating catecholamines (causing dysrhythmias). Other signs of hypoperfusion may also be present, such as dusky skin color, oliguria, and impaired mentation.

The body produces its own “medications,” epinephrine and norepinephrine, in the adrenal glands in response to hypoperfusion. These substances are released by the body as part of the global compensatory state. Release of epinephrine improves cardiac output by increasing the pulse rate and strength of contractions. The alpha-1 response to its release includes vasoconstriction, increased peripheral vascular resistance, and increased afterload from the arteriolar constriction. Alpha-2 effects ensure a regulated release of alpha-1. Beta responses from the release of epinephrine primarily affect the heart and lungs. Increases in pulse rate, contractility, conductivity, and automaticity occur in tandem with bronchodilation.

Effects of norepinephrine are primarily alpha-1 and alpha-2 in nature and center on vasoconstriction and increasing peripheral vascular resistance. **TABLE 14-2** lists the alpha and beta effects of epinephrine and norepinephrine. This vasoconstriction allows the body to shunt blood from areas of lesser need to areas of greater need, keeping the brain and other vital organs perfused in the early phases of shock. To maintain circulation to the brain, the body will shunt blood away from the following tissues in the following order: placenta, skin, muscles, gut, kidneys, liver, heart, lungs. This planned shunting of blood is often referred to as the pecking order. The skin and muscles can survive with minimal blood flow from vasoconstriction for a much longer period than can major organs such as the kidneys, liver, heart, and lungs. If the blood

TABLE 14-2 Effects of Epinephrine and Norepinephrine

Epinephrine	
Alpha-1	Vasoconstriction Increase in peripheral vascular resistance Increased afterload from arteriolar constriction
Alpha-2	Inhibit insulin release Relax gastrointestinal smooth muscle
Beta-1	Positive chronotropic effects (increase in the heart's rate of contraction) Positive inotropic effects (increase in the contractility of the heart muscle) Positive dromotropic effects (increase in the heart's velocity of conduction)
Beta-2	Bronchodilation Gastrointestinal smooth muscle dilation
Norepinephrine	
Alpha-1 and alpha-2	Vasoconstriction Increase in peripheral vascular resistance Increased afterload from arteriolar constriction

supply is inadequate to the major organs for more than 60 minutes, they often develop complications that will result in death, such as renal failure and shock lung. This concept has been traditionally referred to as the Golden Hour or the Golden Period in recognition of the fact that the time frame actually varies with the severity of the disruption in the blood supply and the resilience of the tissues, yet it describes why it is so important for you to treat the cause of the shock immediately.

Failure of compensatory mechanisms to preserve perfusion results in decreases in preload and cardiac output. Myocardial blood supply and oxygenation decrease, reducing myocardial perfusion. As cardiac output further decreases, coronary artery perfusion also decreases, resulting in myocardial ischemia. During these changes, other organ systems are affected too. The normal functions of the liver and pancreas are affected by the low perfusion state inhibiting insulin release, which is why patients in shock have been described as being in a diabetic-like state. Gastrointestinal motility is decreased, causing stress ulcers to develop. When kidney perfusion is diminished, so is urine production; this results in kidney failure if reperfusion does not occur within a sufficient time frame.

Shock-Related Events at the Capillary and Microcirculatory Levels

As perfusion decreases, cellular ischemia occurs. Minimal blood flow passes through the capillaries, causing the cells to switch from aerobic metabolism to anaerobic metabolism (all cell processes occurring in the absence of oxygen), which can quickly result in metabolic acidosis. With reduced circulation, the blood stagnates in the capillaries. The precapillary sphincter relaxes in response to the buildup of lactic acid, vasomotor center failure, and increased amounts of carbon dioxide. The post-capillary sphincters remain constricted, causing the capillaries to become engorged with fluid.

The capillary sphincters—circular muscular walls that constrict and dilate—regulate blood flow through the capillary beds. These sphincters are under the control of the autonomic nervous system, which regulates involuntary functions such as sweating and digestion. Capillary sphincters also respond to other stimuli such as heat, cold,

increased demand for oxygen, and the need for waste removal. Thus, the regulation of blood flow is determined by cellular need and is accomplished by vessel constriction or dilation, working in tandem with sphincter constriction or dilation.

The body can tolerate anaerobic metabolism for only a limited time. Anaerobic metabolism is much less efficient than aerobic metabolism and results in systemic acidosis and depletion of the body's normally high energy reserves (adenosine triphosphate [ATP]). Although hypoxia decreases the rate of ATP synthesis in cells, it will not damage the mitochondria unless it is sustained and severe. During anaerobic metabolism, incomplete glucose breakdown results in an accumulation of pyruvic acid. However, pyruvic acid cannot be converted to acetyl coenzyme A without oxygen, so it is transformed in greater amounts to lactate and other acid by-products, resulting in acidosis.

At the same time, ischemia stimulates increased carbon dioxide production by the tissues. The higher the body's metabolic rate, the higher the carbon dioxide level in hypoperfused states. The excess carbon dioxide combines with intracellular water to produce carbonic acid. Increased tissue acid levels will react with other buffers to form more intracellular acidic substances. Thus, acidosis serves as an indirect measure of tissue perfusion. The acidic condition of the blood inhibits hemoglobin in the RBCs from binding with and carrying oxygen.

Meanwhile, sodium, which is usually more abundant outside the cells than inside them, is naturally inclined to diffuse into the cells. Normally the sodium/potassium pump acts like a “bouncer” at the cell membrane, sending the sodium back out against the concentration gradient. This mechanism involves active transport and requires an ample supply of ATP to fuel the bouncer. Reduced levels of ATP, however, result in a dysfunctional sodium/potassium pump and alter the cell membrane function. Excessive sodium begins to diffuse into the cells, along with water, which ultimately depletes the interstitial compartment.

The intracellular enzymes that usually help digest and neutralize bacteria introduced into a cell are bound in a relatively impermeable membrane inside cells in structures known as lysosomes. Cellular flooding explodes the lysosomal membrane and releases these lysosomal enzymes, which then autodigest the cell. If enough cells are destroyed

in this way, organ failure will become evident. The release of the lysosomes opens the floodgates for the progression of shock to the point where it may quickly be fatal and the damage irreversible.

To compound these problems, accumulating acids and waste products act as potent vasodilators, further decreasing venous return and diminishing blood flow to the vital organs and tissues. The arterial pressure falls to the point at which even the “protected organs” such as the brain and heart are no longer adequately perfused. When aortic pressures fall below a MAP of 60 mm Hg, the coronary arteries no longer fill as effectively, the heart is underperfused, and the cardiac output falls.

Eventually, the reduced blood supply to the vasomotor center in the brain results in slowing and then stopping of sympathetic nervous system activity. The metabolic wastes are released into the slower-flowing blood. The blood’s sluggish flow, coupled with its acidity, results in platelet agglutination and formation of microthrombi. Because the capillary walls are stretched, they lose their ability to retain large molecules, allowing them to leak into the surrounding interstitial spaces. Hydrostatic pressure forces plasma into the interstitial spaces, further increasing the distance from the capillaries to the cells. In turn, oxygen transport decreases, further increasing cellular hypoxia.

The continuing buildup of lactic acid and carbon dioxide acts as a potent vasodilator, resulting in relaxation of the postcapillary sphincters. The accumulated hydrogen, potassium, carbon dioxide, and thrombosed (clotted) RBCs wash out into the venous circulation, increasing the metabolic acidosis. This has been referred to as the capillary wash-out phase. The result is an even greater decrease in cardiac output. This process ultimately results in multiple-organ dysfunction syndrome (MODS), in which various organ systems fail in succession.

In conjunction with all this injury occurring, the white blood cells and blood-clotting system are impaired. There is a decreased resistance to infection, and disseminated intravascular coagulation (DIC) may occur. DIC is a serious disorder whereby the circulating proteins that normally control clotting become depleted and ineffective, resulting in paradoxical spontaneous uncontrolled bleeding while also causing small vessel thrombosis throughout the body, further compromising perfusion to those sites and leading to ischemic injury. Yet again,

a normal function becomes activated under abnormal circumstances. DIC has also been found to complicate **septic shock**.

Words of Wisdom

Capillary hydrostatic pressure tends to force fluids through capillary walls, whereas interstitial fluid hydrostatic pressure pushes fluid back into the cells.

Oncotic pressure pulls fluids from the surrounding tissue into the capillaries as a result of a difference in the concentration of solutes in the fluid inside the capillaries. Fluid leaves the capillaries as a result of hydrostatic pressure, while albumin and other large proteins remain inside, resulting in a greater concentration of solutes inside the capillaries. The oncotic pressure increases, pulling more water into the capillaries to balance the solute concentration. If capillary hydrostatic pressure is greater, fluid will leave the capillaries. If capillary oncotic pressure is greater, fluid will be pulled into the capillaries.

Words of Wisdom

Ion concentration is altered during acidosis and alkalosis. **TABLE 14-3** shows a reminder of increases and decreases during those states. Chapter 8, *Pathophysiology*, discusses acidosis and alkalosis.

Buffer systems respond in the following order:

- Chemical (bicarbonate) buffer
- Respiratory system
- Renal system

TABLE 14-3 Acid-Base Balance

Acidosis	Alkalosis
↓ pH	↑ pH
↑ H ⁺	↓ H ⁺
↑ CO ₂	↓ CO ₂
↓ HCO ₃ ⁻	↑ HCO ₃ ⁻
↑ H ₂ CO ₃	↓ H ₂ CO ₃
Metabolic components include H ⁺ and HCO ₃ ⁻ .	
Respiratory components include CO ₂ and O ₂ .	

Abbreviations: CO₂, carbon dioxide; H⁺, hydrogen ion; HCO₃⁻, bicarbonate; H₂CO₃, carbonic acid; O₂, oxygen; pH, potential of hydrogen

Multiple-Organ Dysfunction Syndrome

Multiple-organ dysfunction syndrome (MODS) is a progressive condition characterized by combined failure of several organs, such as the lungs, liver, and kidneys, along with some clotting mechanisms, which occurs after severe illness or injury. It is a major cause of death following septic, traumatic, and burn injuries.

MODS occurs when injury or infection (as in septic shock) triggers a massive systemic immune, inflammatory, and coagulation response, resulting in the release of numerous inflammatory mediators and activation of the following systems:

- **The complement system.** Normally, this group of plasma proteins functions to eliminate invading bacteria. In MODS, an overactive complement system induces further inflammation and damage to cells.
- **The coagulation system.** Endothelial damage and coagulation, especially in the microscopic venules and arterioles, become uncontrolled in MODS, which results in microvascular thrombus formation and tissue ischemia.
- **The kallikrein-kinin system.** The release of bradykinin, a potent vasodilator, results in tissue hypoperfusion and may contribute to hypotension.

The net outcome of overactivity in these systems is maldistribution of systemic and organ blood flow. Often, tissues attempt to compensate by accelerating their metabolism. The result is an oxygen supply-demand imbalance that leads to tissue hypoxia, tissue hypoperfusion, exhaustion of the cells' fuel supply (ATP), metabolic failure, lysosome breakdown, anaerobic metabolism, acidosis, and impaired cellular function. As MODS progresses, various organs begin to malfunction as a result of cell and tissue hypoxia.

MODS typically develops within hours to days following resuscitation. In a 14- to 21-day period, renal and liver failure can develop, along with collapse of the gastrointestinal and immune systems. If the patient does not respond to treatment of the underlying condition, cardiovascular collapse and death typically occur within days to weeks of the initial injury.

Signs and symptoms of MODS include hypotension; insufficient tissue perfusion; uncontrollable bleeding; and multisystem organ failure caused mainly by hypoxia, tissue acidosis, and severe local alterations of metabolism. Patients can have a low-grade fever from the inflammatory response and are tachycardic and dyspneic. They may prove difficult to oxygenate owing to the presence of adult respiratory distress syndrome. (Adult respiratory distress syndrome is discussed in Chapter 17, *Respiratory Emergencies*.)

Respiratory Impairment

A patient with a severe chest injury, such as flail chest, or obstruction of the airway, may be unable to take in an adequate amount of oxygen. This affects the process of respiration; there is not enough oxygen to meet the metabolic demand.

An insufficient concentration of oxygen in the blood can produce shock as rapidly as vascular causes, even if the volume of blood, the volume of the vessels, and the action of the heart are all normal. Without oxygen, the organs in the body cannot survive, and their cells promptly start to deteriorate.

Certain types of poisoning may affect the ability of cells to metabolize or carry oxygen. Carbon monoxide has a 200- to 250-fold greater affinity for hemoglobin than does oxygen. If patients inhale carbon monoxide, it will bind to the hemoglobin, forming carboxyhemoglobin, rather than allowing oxygen to bind. This results in a hypoxic state if not corrected. Cyanide impairs the ability of cells to metabolize oxygen within the cell, and cellular asphyxia may occur. Pulse oximetry readings are unreliable in cases of carbon monoxide exposure, so end-tidal carbon dioxide (ETCO₂) findings are particularly helpful when treating these patients, and supplemental oxygen administration is essential.

Anemia is defined as an abnormally low number of RBCs. RBCs contain hemoglobin, an iron-containing protein. Hemoglobin transports oxygen from the lungs to the tissues. Each hemoglobin molecule can carry four oxygen molecules. Anemia may be the result of either chronic or acute bleeding, a deficiency in certain vitamins or minerals, or an underlying disease process. If severe anemia is present, tissues may be hypoxic because the blood may not be able to carry adequate oxygen,

FIGURE 14-5 There are three basic causes of shock and impaired tissue perfusion. **A.** Pump failure occurs when the heart is damaged by disease, injury, or obstructive causes. The heart may not generate enough energy to move the blood through the system. **B.** Low fluid volume, often a result of bleeding, leads to inadequate perfusion. **C.** Poor vessel function—if blood vessels dilate excessively, the blood within them, even though it is of normal volume, is inadequate to fill the system and provide efficient perfusion.

© Jones & Bartlett Learning.

even though the hemoglobin is fully saturated. In this situation, a pulse oximeter may indicate that there is adequate saturation, even though the tissues are hypoxic. This type of hypoxia is known as hypoxemic hypoxia.

Causes of Shock

Shock can result from many conditions, including bleeding, respiratory failure, acute allergic reactions, and overwhelming infection. In all cases, however, the damage occurs because of insufficient perfusion of organs and tissues. As soon as perfusion stops or becomes impaired, tissues start to die, affecting all local body processes. If the conditions causing shock are not promptly arrested and reversed, death soon follows.

You should have a high index of suspicion for shock in many emergency medical situations. For example, you would expect **hemorrhagic shock** to accompany massive external or internal bleeding. You should also expect shock if a patient has any one of the following conditions:

- Multiple severe fractures
- Abdominal or chest injury
- Spinal injury
- A severe infection
- A major heart attack (acute myocardial infarction)
- **Anaphylaxis**

Understanding the basic physiologic causes of shock will better prepare you to treat it. There are three basic causes of shock (**FIGURE 14-5**).

Words of Wisdom

Shock is a complex physiologic process that gives subtle signs to its presence before it becomes severe. These early signs relate very closely to the events that result in more severe shock, so it is important for you to know the underlying processes thoroughly. If you understand what causes shock, you will be able to recognize it in many patients before it becomes out of control.

Types of Shock

Shock may be the result of a variety of causes, but hypovolemia from blood or fluid loss is a common culprit. **TABLE 14-4** explains the differences between the types of nonhypovolemic shock and how to differentiate them from **hypovolemic shock** (shock that arises from inadequate blood volume). Specific types of shock are discussed next.

Hypovolemic Shock

When shock comes about because of inadequate blood volume, it is termed *hypovolemic shock* (*hypo* = deficient + *vol* = volume + *emia* = in the

TABLE 14-4 Differentiating Nonhypovolemic Causes of Shock

Type	How to Differentiate
Cardiogenic shock	Differentiated from hypovolemic shock by the presence of one or more of the following: • Chief complaint: chest pain, dyspnea, tachycardia • Heart rate: bradycardia or excessive tachycardia • Signs of heart failure: jugular vein distention, rales • Dysrhythmias
Distributive shock	Differentiated from hypovolemic shock by the presence of one or more of the following: • Mechanism that suggests vasodilation: spinal cord injury, drug overdose, sepsis, anaphylaxis • Warm, flushed skin, especially in dependent areas • Lack of tachycardic response: this is not reliable because a substantial number of hypovolemic patients never experience tachycardia.
Obstructive shock	Differentiated from hypovolemic shock by the presence of signs and symptoms suggestive of: • Cardiac tamponade • Tension pneumothorax • Pulmonary embolism

© Jones & Bartlett Learning.

blood). There are hemorrhagic and nonhemorrhagic causes of hypovolemic shock. Volume can be lost as blood (internal or external hemorrhagic shock), or as plasma (burns) or electrolyte solution (vomiting, diarrhea, sweating), known as nonhemorrhagic shock.

Nonhemorrhagic hypovolemic shock will be discussed in this chapter. See Chapter 27, *Bleeding*, for information on treatment of hemorrhagic shock.

Nonhemorrhagic shock occurs when the fluid loss is contained within the body, as in dehydration, burn injury, crush injury, and anaphylaxis. With severe thermal burns, for example, intravascular plasma leaks from the circulatory system into the burned tissues that are adjacent to the injury. By comparison, crushing injuries may result in the loss of blood and plasma from damaged (crushed) vessels into injured tissues.

Abnormal losses of fluids and electrolytes (dehydration) may occur through a variety of mechanisms listed as follows:

- Gastrointestinal losses, especially through vomiting and diarrhea
- Increased loss as a result of fever, hyperventilation, or high environmental temperatures (through the lungs)

- Increased and excessive sweating
- Internal losses (“third-space” losses), as in peritonitis, pancreatitis, and ileus
- Plasma losses from burns, drains, and granulating wounds

Other causes of body fluid deficits include ascites (buildup of free fluid in the abdomen), diabetes insipidus (inappropriate excretion of excess fluid from the kidneys), and osmotic diuresis secondary to hyperosmolar states (ie, diabetic ketoacidosis).

Most of the typical symptoms and signs of shock result from inadequate tissue oxygenation and the body’s attempts to compensate for volume loss. The earliest signs of shock are restlessness and anxiety: the patient looks scared! The decline in tissue perfusion may not be enough to produce obvious asphyxia, but it *is* setting off alarms all over the body, to which the patient responds with a feeling of apprehension—a “gut” feeling that something is not right. If alert, the patient may report being thirsty, reflecting the deficit of fluids in the body; at the same time, the patient may feel nauseated and even vomit. The diversion of blood flow away from low-priority peripheral tissues causes the skin to become pale, cold, and clammy; sometimes it has a mottled appearance. Meanwhile, the heart speeds

up to circulate the remaining RBCs more rapidly, producing a rapid, weak pulse—rapid because the heart is beating faster, weak because the blood vessels are now narrow and the volume moving through them is decreased.

In each case, the fluid lost has a unique electrolyte composition, and long-term therapy aims to restore the deficient body chemicals. For treatment in the field, however, all excessive fluid losses can be considered to result in dehydration.

Symptoms of dehydration include loss of appetite (anorexia), nausea, vomiting, and sometimes fainting when standing up (postural syncope). Physical examination of a dehydrated patient reveals poor skin turgor (the skin over the forehead or sternum will tent when pinched); a shrunken, furrowed tongue; and sunken eyes. The pulse will be weak and rapid, rising more than 15 beats/min when the patient is raised from a recumbent to a sitting position (a maneuver that may cause the patient to feel faint). When fluid and electrolyte depletion are severe, shock and coma may be present.

As bleeding or fluid loss continues, the blood pressure finally falls in the shock patient. Do not wait until the blood pressure falls before you suspect shock and begin treatment! Falling blood pressure is a *late* sign in shock (decompensated shock, discussed later), signaling the collapse of all compensatory mechanisms and the fact that the patient may have already lost 30% or more fluid volume. Furthermore, the blood pressure measured at the arm provides you with little information about perfusion of vital organs; it tells only about perfusion of the arms.

TABLE 14-5 summarizes the signs and symptoms of hypovolemic shock.

The goal in treating shock is to save the brain, lungs, and kidneys; these organs must remain perfused if the patient is to survive and return to a healthy life. The best indication of brain perfusion is the patient's level of consciousness (LOC). If the

patient is alert and oriented, the brain is being perfused adequately despite what the blood pressure findings show. If the patient has an altered mental status, perfusion of the brain is inadequate.

Cardiogenic Shock

Cardiogenic shock is caused by inadequate function of the heart, or pump failure. Circulation of blood throughout the vascular system requires the constant pumping action of a normal and vigorous heart muscle. Many diseases or injuries can cause destruction or inflammation of this muscle. Within certain limits, the heart can adapt to these problems. However, if too much muscular damage occurs, as sometimes happens after a massive heart attack, the heart no longer functions well. A major effect is the backup of blood into the lungs. The resulting buildup of fluid within the pulmonary tissue is called pulmonary edema. **Edema** is the presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area (**FIGURE 14-6**). Pulmonary edema results in impaired ventilation, which may be manifested by

FIGURE 14-6 Pulmonary edema develops as a result of fluid buildup within the pulmonary tissue. The edema causes swelling and results in impaired ventilation.

TABLE 14-5 Signs and Symptoms of Hypovolemic Shock

- Mental status changes
- Rapid, weak pulse
- Thirst
- Low blood pressure (late sign)
- Cool, clammy, pale skin

an increased respiratory rate and abnormal breath sounds secondary to fluid buildup within the alveoli.

The muscular contraction of the heart moves blood through the vessels at distinct pressures. For blood to circulate efficiently throughout the entire system, there must be the right amount of pressure and an adequate number of heartbeats. For this reason, the heart has its own electrical system that initiates and regulates its beating. Disease or injury can damage or destroy this system, causing irregular and uncoordinated beats, a heart rate that is too slow (fewer than 60 beats/min), or a heart rate that is too fast (more than 100 beats/min).

Cardiogenic shock develops when the heart cannot maintain sufficient output (cardiac output) to meet the demands of the body. In general, as afterload increases, cardiac output decreases. Increased afterload may also cause the heart to overwork while trying to maintain adequate cardiac output. High afterload is often the reason that heart failure develops in patients with hypertension. Cardiogenic shock may result from low cardiac output due to high afterload, low preload, poor contractility, or any combination of the three.

Obstructive Shock

Obstructive shock results when conditions that cause mechanical obstruction of the cardiac muscle also affect pump function. Three of the most common examples of obstructive shock are cardiac tamponade, tension pneumothorax, and pulmonary embolism.

Cardiac tamponade, or pericardial tamponade, occurs when blood leaks into the tough fibrous membrane known as the pericardium, causing an accumulation of blood within the pericardial sac. It is caused by blunt or penetrating trauma and can progress rapidly. This accumulation results in compression of the heart. Because the pericardium has a limited ability to stretch, each contraction of the heart allows more blood accumulation between the heart and the sac. The accumulated blood prevents the heart from opening up to allow complete refilling. Continued pressure within the pericardial sac obstructs the flow of blood into the heart, resulting in decreased outflow from the heart. Signs and symptoms of cardiac tamponade are referred to as the Beck triad, and include the presence of jugular

venous distention, muffled heart sounds, and a narrowing **pulse pressure** (the difference between the systolic and diastolic pressures).

Another obstructive condition occurs with a tension pneumothorax. A tension pneumothorax is caused by damage to the lung tissue. This damage allows air normally held within the lung to escape into the chest cavity. If a pneumothorax progresses, a sufficient amount of air will accumulate within the chest cavity and begin applying pressure to the structures in the mediastinum. The primary organs in this area are the heart and great vessels (aorta, venae cavae, and pulmonary arteries and veins). When the trapped air begins to shift the chest organs toward the uninjured side, a pneumothorax becomes known as a tension pneumothorax, which is a serious and life-threatening condition. As pressure from one side of the chest begins to push the mediastinum toward the other side, the vena cava loses its ability to stay fully expanded. This mechanical compression of the vessel results in reduced return of blood to the heart. The patient becomes anxious and short of breath. The heart and respiratory rates increase and become shallower. Blood pressure decreases. You may notice difficulty when attempting to ventilate the patient with a bag-mask device. The affected side will have decreased or absent breath sounds and the patient will become cyanotic. Tracheal deviation is a late sign of tension pneumothorax.

A massive, centrally located pulmonary embolism can also result in obstructive shock. A pulmonary embolism is a blood clot that occurs in the pulmonary circulation and blocks the flow of blood through the pulmonary vessels. When a massive pulmonary embolism occurs, it can prevent blood from being pumped from the right side of the heart to the left, resulting in complete backup of blood in the right ventricle and leading to catastrophic obstructive shock and complete pump failure.

Distributive Shock

Distributive shock results when there is widespread dilation of the small arterioles, small venules, or both. As a result, the circulating blood volume pools in the expanded vascular beds and tissue perfusion decreases. The four most common types of distributive shock are septic shock, **neurogenic shock**, **anaphylactic shock**, and **psychogenic shock**.

Septic Shock

Septic shock occurs as a result of severe infections, usually bacterial, in which toxins (poisons) are generated by the bacteria or by infected body tissues. In this condition, the toxins damage the vessel walls, causing increased cellular permeability. The vessel walls leak and are unable to contract well. Widespread dilation of vessels, in combination with plasma loss through the injured vessel walls, results in shock.

Septic shock is a complex problem. First, there is an insufficient volume of fluid in the container, because much of the plasma has leaked out of the vascular system (hypovolemia). Second, the fluid that has leaked out often collects in the respiratory system, interfering with ventilation. Third, the vasodilation results in a larger-than-normal vascular bed to contain the smaller-than-normal volume of intravascular fluid.

Septic shock presents similarly to hemorrhagic shock in that the patient will have a weak, thready pulse; shallow, rapid respirations; and altered mental status. One major difference is that patients with

septic shock often present with warm or hot skin as a result of the elevated core body temperature associated with the infection. Septic shock is almost always a complication of a serious illness, injury, or surgery.

Neurogenic Shock

Damage to the spinal cord, particularly at the upper cervical levels, may cause substantial injury to the part of the nervous system that controls the size and muscular tone of the blood vessels. Neurogenic shock is usually the result. Although not as common, there are medical causes as well. These include brain conditions, tumors, and pressure on the spinal cord. In neurogenic shock, the muscles in the walls of the blood vessels are cut off from the sympathetic nervous system and nerve impulses that cause them to contract. This prevents the natural catecholamine release that is seen with other types of shock and results in the classic symptoms. As a result of the lack of sympathetic innervation, all vessels below the level of the spinal injury dilate widely, increasing the size and capacity of

YOU are the Provider

Part 2

You identify that the patient is exhibiting signs and symptoms of hypoperfusion. Your partner places a nonbreathing mask on the patient and administers oxygen at 15 L/min. You continue your primary survey and find no other life threats. While performing your secondary assessment, you note a distended abdomen that is tender to palpation. Your SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) reveals that the patient has no allergies and has a history of hypertension and peptic ulcers. He has been unable to eat since last night and reports a “burning” pain in his epigastric region. There is no incidence of trauma or physical activity. You send your partner to retrieve the stretcher.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	25 breaths/min, labored and irregular
Circulation	Cool, clammy, pale

3. Which type of shock do you suspect this patient is experiencing?
4. Which stage of shock is this patient experiencing?

FIGURE 14-7 Damage to the spinal cord can result in nerves no longer being able to make the vessels contract. Instead, vessels dilate widely. The blood in the body can no longer fill the enlarged vessels; inadequate perfusion results.

© Jones & Bartlett Learning.

the vascular system and causing blood to pool (**FIGURE 14-7**). The available 6 L of blood in the body can no longer fill the enlarged vascular system. Even though no blood or fluid has been lost, perfusion of organs and tissues becomes inadequate, and shock occurs. In this condition, a radical change in the size of the vascular system has caused shock. Characteristic signs of this type of shock are the absence of sweating below the level of injury; normal, warm skin; and the lack of an elevated pulse.

Words of Wisdom

With neurogenic shock, many other functions that are under the control of the same part of the nervous system are also lost. The most important of them, in an acute injury setting, is the ability to control body temperature. Body temperature in a patient with neurogenic shock can rapidly fall to match that of the environment. In many situations, substantial hypothermia occurs, severely complicating the situation. **Hypothermia** is a condition in which the internal body temperature falls below 95°F (35°C), usually after prolonged exposure to cool or freezing temperatures. Maintenance of body temperature is always an important element of treatment for a patient in shock.

Words of Wisdom

Microcirculation is a term used to describe the small vessels in the vasculature that are embedded within organs and responsible for the distribution of blood within tissues. Capillaries are part of microcirculation. They branch off the arterioles and allow for exchange between cells and circulation. The arteriole-venule shunts are short vessels that connect the arteriole and venule at opposite sides, bypassing the capillary beds. The main functions of microcirculation include the regulation of blood flow and tissue perfusion, blood pressure, tissue fluid, delivery of oxygen, removal of carbon dioxide, and the regulation of body temperature and inflammation.

Anaphylactic Shock

Anaphylaxis, or anaphylactic shock, occurs when people react violently to a substance to which they have been sensitized. **Sensitization** means becoming sensitive to a substance that did not initially cause a reaction. Do not be misled by a patient who reports no history of allergic reaction to a substance on first or second exposure. Each subsequent exposure after sensitization tends to produce a more severe reaction.

In anaphylactic shock, there is no loss of blood, no mechanical vascular damage, and only a slight possibility of direct cardiac muscular injury. Instead, there is widespread vascular dilation, increased permeability, and bronchoconstriction. The combination of poor oxygenation and poor perfusion in anaphylactic shock may easily prove fatal.

In anaphylaxis, immune system chemicals, such as histamine and other vasodilator proteins, are released when exposed to an allergen. Their release causes the severe bronchoconstriction that accounts for wheezing if the patient is actually moving enough air. Anaphylaxis is also accompanied by urticaria (hives). The results are widespread vasodilation, which causes distributive shock, and blood vessels that continue to leak. Fluid leaks out of the blood vessels and into the interstitial space, resulting in hypovolemia and potentially causing substantial swelling. In some cases, this swelling may occlude the upper airway, resulting in a life-threatening condition.

Instances that cause severe allergic reactions commonly fall into the following four categories of exposure:

- Injections (tetanus antitoxin, penicillin)
- Stings (honeybee, wasp, yellow jacket, hornet)
- Ingestion (shellfish, nuts, fruit, medication)
- Inhalation (dust, pollen)

Anaphylactic reactions can develop within minutes or even seconds after contact with the substance to which the patient is allergic. The signs of such allergic reactions are distinct and not seen with other forms of shock. Signs of anaphylactic shock are summarized later in this chapter. Note that **cyanosis** (blue color of the skin) is a late sign of anaphylactic shock. Additional discussion of anaphylactic shock can be found in Chapter 22, *Immunologic Emergencies*.

Recurrent large areas of subcutaneous edema of sudden onset, usually disappearing within 24 hours, are called **angioedema**.

Psychogenic Shock

A patient in psychogenic shock has had a sudden reaction of the nervous system that produces a temporary, generalized vascular dilation, resulting in fainting, or **syncope**. Blood pools in the dilated vessels, reducing the blood supply to the brain; as a result, the brain ceases to function normally, and the patient faints. Whereas there are many causes of syncope, it is important to realize that some are of a serious nature but others are not. Causes of syncope that are potentially life-threatening result from events such as an irregular heartbeat or a brain **aneurysm**. Other non-life-threatening events that cause syncope may be the receipt of bad news or experiencing fear or unpleasant sights (such as the sight of blood). While psychogenic shock is considered a non-life-threatening cause of syncope, it is generally a diagnosis of exclusion, meaning the diagnosis is made after more serious potential causes of syncope have been thoroughly and appropriately excluded. Psychogenic shock may be suspected but is never definitively diagnosed in the out-of-hospital environment.

Words of Wisdom

The AEMT should never assume psychogenic shock and always treat for more serious potential causes until the diagnosis is made by trained hospital personnel.

TABLE 14-6 summarizes potential causes and signs and symptoms of the various types of shock.

Words of Wisdom

Mental status is the best determinant of how well the brain and likely the other vital organs are being perfused.

Words of Wisdom

You should consider any patient exhibiting signs and symptoms of shock without obvious external injury to have probable internal bleeding, usually in the abdominal cavity.

Special Populations

When you are treating pediatric patients, remember that their bodies can compensate well until they have lost about 30% to 35% of their blood volume; then their condition declines rapidly. Their ability to compensate relies on an increasing pulse rate and SVR. These measures cause the body to rapidly burn glucose. Unfortunately, children have little stored glucose.

Pediatric patients compensate through vasoconstriction and increased peripheral vascular resistance, but this is not enough to perfuse the brain, heart, and lungs to stay alive. Blood pressure may be the last measurable factor to change in shock. By the time you detect a decrease in blood pressure, shock is well developed. This is particularly true in infants and children, who can maintain their blood pressure until they have lost more than one-half of their blood volume. To maintain coronary and cerebral perfusion, peripheral vasoconstriction manifests as cool distal extremities, weakened distal pulses, and delayed capillary refill in extremities. By the time blood pressure decreases in infants and children who are in shock, they are close to death. Never wait to see a decrease in the systolic blood pressure to aggressively manage a child you suspect may be in the early phase of shock.

Treat pediatric patients aggressively and early if there is any indication of developing shock. Provide oxygen, manage the body temperature, place the patient in the appropriate position, and initiate intravenous (IV) access en route to the appropriate facility. See Chapter 36, *Pediatric Emergencies*, for more information on shock in pediatric patients.

TABLE 14-6 Potential Causes and Signs and Symptoms of Various Types of Shock

Type of Shock	Examples of Potential Causes	Signs and Symptoms
Cardiogenic	Inadequate heart function Disease of muscle tissue Impaired electrical system Disease or injury	Chest pain Irregular pulse Weak pulse Low blood pressure Cyanosis (lips, under nails) Cool, clammy skin Anxiety Crackles (rales) Pulmonary edema
Obstructive	Mechanical obstruction of the cardiac muscle causing a decrease in cardiac output 1. Tension pneumothorax 2. Cardiac tamponade 3. Pulmonary embolism	Dependent on cause: • Dyspnea • Rapid, weak pulse • Rapid, shallow breaths • Decreased lung compliance • Unilateral, decreased, or absent breath sounds • Decreased blood pressure • Jugular vein distention • Subcutaneous emphysema • Cyanosis • Tracheal deviation toward affected side • Beck triad (cardiac tamponade): • Jugular vein distention • Narrowing pulse pressure • Muffled heart tones
Septic	Severe bacterial infection	Warm skin or fever Tachycardia Low blood pressure
Neurogenic	Damaged cervical spine, which causes widespread blood vessel dilation	Bradycardia (slow pulse) or normal pulse Low blood pressure Signs of neck injury
Anaphylactic	Extreme life-threatening allergic reaction	Can develop within seconds Mild itching or rash Burning skin Vascular dilation Generalized edema Coma Rapid death
Psychogenic (fainting)	Temporary, generalized vascular dilation Anxiety, bad news, sight of injury or blood, prospect of medical treatment, severe pain, illness, tiredness	Rapid pulse Normal or low blood pressure
Hypovolemic	Loss of blood or fluid	Rapid, weak pulse Low blood pressure Change in mental status Cyanosis (lips, under nails) Cool, clammy skin Increased respiratory rate

The Progression of Shock

Shock occurs in two successive stages—compensated and decompensated. Although you cannot see shock, you can see its signs and symptoms (**TABLE 14-7**). The early stage of shock, while the body can still compensate for blood loss, is called **compensated shock** (nonprogressive shock). The late stage, when blood pressure is falling, is called **decompensated shock** (progressive shock). Sometimes the term **irreversible shock** is used to describe shock that has progressed to a terminal stage.² In this case, even if the cause of shock is treated and reversed, vital organ damage may be permanent and the patient may eventually die.

Words of Wisdom

Your goal as an AEMT is to recognize the signs of the early stages of shock and begin immediate treatment before permanent damage occurs. To accomplish this, you must be aware of the subtle signs exhibited in compensated shock and treat the patient aggressively. Anticipate the potential for shock from the scene size-up. Recognize the signs of poor perfusion that precede hypotension, and do not rely on any one sign or symptom to determine the degree of shock. Always err on the side of caution when treating a potential shock patient. Rapid assessment and immediate transportation are essential to minimize organ damage and to preserve any chance of patient survival.

TABLE 14-7 Progression of Shock

Stage	Signs and Symptoms
Compensated shock	• Agitation, anxiety, restlessness • Sense of impending doom • Weak, rapid (thready) pulse • Clammy (cool, moist) skin • Pallor, with cyanotic lips • Shortness of breath • Nausea, vomiting • Delayed capillary refill in infants and children • Thirst • Narrowing pulse pressure
Decompensated (progressive) shock	• Altered mental status (verbal to unresponsive)^a • Hypotension (systolic blood pressure of 90 mm Hg or lower in an adult) • Narrowing of the pulse pressure, indicating impairment of circulation • Labored or irregular breathing • Thready or absent peripheral pulses • Additional increase in pulse and respirations • Ashen, mottled, or cyanotic skin • Dull eyes, dilated pupils • Diminished urine output • Diaphoresis • Thirst (the body's call for increased volume) • Decreased capillary refill time • Dry mucosa • Nausea and vomiting (caused by shunting of blood from abdominal organs)
Irreversible shock	• Marked decrease in level of responsiveness (Glasgow Coma Scale score <7) • Decreased respiratory rate and effort • Inability to palpate a pulse • Decrease in pulse rate • Profound hypotension • Impending cardiac arrest • Appears moribund or dead

^aMental status changes are late indicators.

Compensated Shock

Compensated shock is the earliest stage of shock. At this stage, the level of responsiveness is a better indicator of tissue perfusion than most other vital signs. Release of chemical mediators by the autonomic nervous system as it recognizes a potential catastrophic event causes the arterial blood pressure to remain normal or slightly elevated. There is an increase in the rate and depth of respirations to bring in more oxygen and remove more carbon dioxide. This helps to maintain the acid-base balance by creating respiratory alkalosis to offset the metabolic acidosis.

At this stage, the blood pressure is maintained. There is a narrowing of the pulse pressure, which is the difference between the systolic and diastolic pressures.

Pulse pressure = Systolic pressure – Diastolic pressure

The pulse pressure reflects the tone of the arterial system and is more sensitive to changes in perfusion than the systolic or diastolic blood pressure

alone. Patients in the compensated stage may have positive **orthostatic vital signs** (an increase in pulse rate and decrease in systolic blood pressure when changing from a supine position to a sitting or standing position, which is commonly seen with dehydration). Treatment at this stage will typically result in recovery.

Decompensated Shock

The next stage, decompensated shock, is when blood pressure is falling; blood volume decreases more than 30%. The compensatory mechanisms are beginning to fail, and signs and symptoms are much more obvious. Cardiac output falls dramatically, resulting in further reductions in blood pressure and cardiac function. The signs and symptoms become more obvious as blood is shunted to the brain, heart, lungs, and kidneys. At this point, vasoconstriction can have a disastrous effect if allowed to continue. Cells in the nonperfused tissues become hypoxic, resulting in anaerobic metabolism. Treatment at this stage will sometimes result in recovery.

YOU are the Provider

Part 3

You assess the patient's vital signs. He has absent radial pulses and you note that his carotid pulse is rapid. A decision is made to establish an IV line and initiate fluid resuscitation based on his blood pressure, skin condition, and the absence of radial pulses. You insert an 18-gauge catheter in the patient's right antecubital fossa and initiate a bolus of normal saline, monitoring carefully for a return of radial pulses. While you are transferring the patient to the stretcher, he reports severe dizziness and has a brief syncopal episode. You and your partner quickly place the patient in the ambulance and begin rapid transport to the closest emergency department (ED).

Recording Time: 8 Minutes

Respirations	26 breaths/min, irregular
Pulse	160 beats/min, regular
Skin	Clammy, cool, pale
Blood pressure	72/40 mm Hg
Oxygen saturation (SpO₂)	98% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERLLA)

- How much IV fluid should this patient receive?
- How should the patient be positioned on the stretcher for transport?

Special Populations

You must use caution when caring for geriatric patients. As a result of the aging process, older patients generally have more serious complications than younger patients. Although illness is a common problem among the geriatric population, you must understand that it is not just part of aging. When treating these patients, keep in mind the following physiologic changes that accompany the aging process:

- The central nervous system often has a delayed response.
- The cardiovascular system has a variety of changes that result in a decrease in the efficiency of the system. On assessment, be alert for higher resting heart rates and irregular pulse rates.
- The respiratory system undergoes substantial changes as the elasticity of the lungs and their size and strength decrease. On assessment, be alert for higher respiratory rates, lower tidal volume, and a decreased gag reflex. In addition, you must remember that cervical arthritis may be present and that dentures may cause an airway obstruction.
- The skin becomes thinner, drier, less elastic, and more fragile, thus providing less protection and thermal regulation (cold and hot).
- The renal system decreases in function and may not respond well to unusual demands such as illness.
- The gastrointestinal system sustains changes in gastric motility that may result in slower gastric emptying.

Along with the normal physiologic changes associated with aging, it is important to remember that medications may interfere with normal coping mechanisms and the patient may not exhibit the same signs and symptoms of shock as another patient. Beta-blockers and calcium channel blockers are common medications used for hypertension and cardiac conditions that may prevent compensation.

Irreversible Shock

In what is sometimes called the irreversible stage, arterial blood pressure is abnormally low. A rapid deterioration of the cardiovascular system occurs that cannot be reversed by compensatory mechanisms or medical interventions. There are life-threatening reductions in cardiac output, blood pressure, and tissue perfusion. Blood is shunted away from the liver, kidneys, and lungs to keep the heart and

brain perfused. Cells begin to die, and even if the cause of shock is treated and reversed, vital organ damage cannot be repaired, and the patient may eventually die. The distinction between decompensated shock and irreversible shock is made based on the failure of the shock state to reverse with appropriate treatment, including surgical intervention if appropriate and intensive care management. It is not possible to distinguish irreversible shock from severe decompensated shock in the prehospital environment.

Patient Assessment

Scene Size-up

As you approach the scene, be alert to potential hazards to your safety. Once on scene, look for and address hazards and threats to the safety of the crew, bystanders, and the patient. If this is a trauma scene or bleeding is suspected, put on gloves and eye protection, at a minimum. Put several pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding.

Safety

When you are caring for a bleeding patient or a patient with severe vomiting or diarrhea, be sure to take necessary precautions to protect yourself from splashing or splattering. Wear appropriate protective equipment including gloves, gown, mask, and eye protection. This is especially essential when arterial bleeding is present. Also remember that frequent, thorough handwashing between patients and after every call is a simple yet important protective measure.

Words of Wisdom

When you first visualize your patient, quickly form an initial general impression. This includes age, sex, signs of distress, obvious life-threatening injuries, abnormal positioning, and skin color. These observations will help you develop an early sense of urgency for care of a patient who appears "sick."

When you first see the patient, observe the scene and patient for clues to determine the nature of the illness or the mechanism of injury. This could help you anticipate the potential for development of shock. Remember that the more traumatic injuries a patient has sustained, the less likely the patient will be able to compensate.

Primary Survey

The primary survey for a patient with suspected shock should include a rapid full-body scan of the patient to determine LOC, identify and manage life-threatening concerns, and determine priority of the patient and transport. Threats to circulation, airway, or breathing are considered life threatening and must be treated *immediately* to prevent mortality.

Life-threatening bleeding should be treated first. A patient with massive hemorrhage may require a tourniquet (or direct pressure dressings when tourniquets are not feasible or available) prior to opening the airway. When possible, direct another rescuer to control bleeding and continue your assessment of the airway and breathing. Treatment of shock should begin as quickly as possible once initial life threats are addressed. Such treatment includes administering high-flow oxygen to assist in perfusion of damaged tissues. Also, early in your assessment, determine the need for manual spinal motion restriction.

After addressing life-threatening bleeding, quickly assess the airway to ensure it is patent. If the patient is awake and answering questions, the airway is patent. Be alert to abnormal airway sounds such as gurgling (suction the airway) or stridor, indicating partial airway obstruction. Consider an adjunct such as an oropharyngeal or nasopharyngeal airway combined with assisted ventilations for a patient with airway impairment and inadequate ventilations.

Quickly assess the patient's breathing. Observe the patient for signs of accessory muscle use such as the muscles of the neck, intercostal retractions, or abnormal use of the abdominal muscles. An increased respiratory rate is often an early sign of impending shock. Assess the patient's breath sounds with a stethoscope, listening for wheezes or other abnormal breath sounds.

Assessing the patient's circulatory status can reveal important clues regarding the presence of shock. Check for the presence of a distal pulse. If you cannot obtain a distal pulse, assess for a central pulse. If the patient has no pulse and is not breathing, immediately begin cardiopulmonary resuscitation (CPR). Quickly determine if the pulse is fast, slow, weak, strong, or altogether absent. A rapid pulse suggests compensated shock. In shock or compensated shock, the skin may be cool, clammy, or ashen. Assess skin temperature, condition, and color; also check for capillary refill time. Maintain a high index of suspicion for occult injuries, especially when the patient is exhibiting signs of shock with no obvious cause.

If the patient shows signs of hypoperfusion, gain IV access, treat aggressively, and provide rapid transport to the closest, most appropriate facility. Request paramedic backup as necessary to assist with more aggressive shock management.

Sometimes, local protocols dictate that a patient should be transported to the nearest hospital for stabilization prior to transfer to a definitive treatment center. If travel time is lengthy, air medical transportation may be the best option. Rapid transport to an appropriate facility without unnecessary scene delays is imperative. Administer fluid en route. Do not delay transport to complete non-life-saving treatments such as splinting extremity fractures; instead, perform these treatments en route.

Also provide psychological support en route. Even unresponsive patients can sometimes hear and understand. Remember to speak calmly and reassuringly to the patient throughout assessment, care, and transport.

Words of Wisdom

For the patient exhibiting signs of a tension pneumothorax, needle chest decompression (performed in-hospital or by paramedics) is necessary to improve cardiac output. In cases of suspected cardiac tamponade, you must recognize the need for expeditious transport for pericardiocentesis at the ED. Either of these conditions further impairs circulation by compression of the heart and decreasing cardiac output.

History Taking

After the life threats have been managed during the primary survey, determine the chief complaint. You should obtain a medical history and be alert for injury-specific signs and symptoms that might cause you to look for evidence of trauma as an etiology for the patient's complaints as well as any pertinent negatives such as loss of sensation.

Quickly obtain a SAMPLE history from the patient. Remember, if the patient experiences a substantial change in LOC before arrival at the hospital, you should provide the hospital personnel with this important information. Note that patients taking beta-blockers or calcium channel blockers are less able to compensate for hypoperfusion or early shock because their vessels do not vasoconstrict as well as a result of the medication they are taking. Also, blood thinners can make bleeding injuries considerably worse.

Secondary Assessment

Begin the secondary assessment by repeating the primary survey to identify injuries not yet found, then follow with a focused assessment. In some instances, such as a critically injured or ill patient or short transport time, you may not have time to conduct a secondary assessment.

If substantial trauma has likely affected multiple systems, start with a full-body exam to be sure that you have identified all injuries.

If your patient is one who gives you a poor general impression or is not responsive, or if you found problems in the primary survey, perform a rapid full-body scan. These scans should be performed quickly but thoroughly to ensure that you do not miss any substantial or life-threatening problems or delay needed care.

Whether your examination is rapid or focused, if a life-threatening problem is found, treat it immediately.

When time permits and the patient's condition is stable, perform a thorough examination of the patient. This includes a complete neurologic assessment.

Obtain a complete set of baseline vital signs. If the patient's condition is unstable or could become

unstable, reassess vital signs every 5 minutes. If the patient is in stable condition, reassess vital signs every 10 to 15 minutes. Baseline vital signs will help you track changes in your patient that correlate to the progression of shock.

In addition to hands-on assessment, you should use monitoring devices to quantify the patient's oxygenation and circulatory status. Use a pulse oximeter to evaluate the effectiveness of oxygenation. Use a manual technique to monitor blood pressure first (a sphygmomanometer and stethoscope), before using a noninvasive blood pressure monitor. Use a glucometer to monitor blood glucose levels.

Words of Wisdom

Just as they make for thorough written reporting, taking and recording frequent vital signs—and observing perfusion indicators such as skin condition and mental status—will give you a window into the progression of shock in your patient. Use your documentation to remind you to suspect shock early and treat it aggressively.

Reassessment

Reassessment is extremely important in caring for a patient. The rule of thumb is assess, intervene, reassess. This portion of the assessment revisits the primary survey, the vital signs, the chief complaint, and any treatment performed on the patient, including oxygen administration. You must assess the patient to determine whether the interventions you performed are having any effect on the patient. This step prepares you to present the patient at the hospital with a complete, concise account of the patient encounter and care.

You must determine what interventions are needed for your patient at this point based on the findings of your assessment. Focus on supporting the cardiovascular system. Treating for shock early and aggressively will help to prevent inadequate perfusion from harming your patient. Specific interventions are discussed in the emergency medical care section later in this chapter.

Special Populations

In older patients, dizziness, syncope, or weakness may be the first sign of nontraumatic internal hemorrhage or cardiac dysrhythmias.

Patients who are in decompensated shock will need rapid interventions to restore adequate perfusion. The hospital may or may not have suggestions on how best to support a patient's failing cardiovascular system. Most of the interventions used to treat shock do not require a specific physician's order; however, some do. Determine, based on the signs and symptoms found in your assessment, whether your patient is in compensated or decompensated shock. Document these findings after you have treated for shock.

Emergency Medical Care for Shock

As mentioned, much of your treatment for shock will begin during the assessment process as soon as you discover life threats and realize shock may be

present. Key interventions are addressing life-threatening bleeding, and airway and breathing concerns.

Control all obvious external bleeding. These include placing dry, sterile dressings over the bleeding sites, securing with bandages, and applying a tourniquet if direct pressure does not rapidly control bleeding from an extremity. Additional information on bleeding control can be found in Chapter 27, *Bleeding*.

Another key intervention is placing the patient in the position dictated by local protocol for shock patients. This will usually be a supine position. Some patients may find it easier to breathe in a sitting or semisitting position. If spinal motion restriction is indicated, splint the patient on a backboard.

Further key interventions are to provide warmth, gain IV access, and administer fluid as needed based on patient presentation. To prevent the loss of body heat, place blankets under and over the patient. Be careful not to overload the patient with covers or attempt to warm the body too much; it is best for the patient to maintain a normal body temperature. Do not use external heat sources, such as hot water bottles or heating pads. They may harm a patient in shock by causing vasodilation and decreasing blood pressure even more.

YOU are the Provider

Part 4

En route, you reassess the patient's vital signs and note that the radial pulse is barely palpable and the carotid pulse has increased slightly. His skin continues to be pale and diaphoretic. You elect to give a second bolus and to establish a second peripheral IV line in the left arm and administer normal saline at a to-keep-open (TKO) rate. You also note that the patient's abdomen is becoming more distended and rigid during the transport. His Glasgow Coma Scale score is evaluated at a 10. In anticipation of further deterioration, you prepare the bag-mask device. You notify the receiving hospital of the patient's condition and your arrival of 10 minutes. While preparing additional equipment that you may need, you arrive at the ED. No further changes are noted on arrival at the hospital.

Recording Time: 16 Minutes

Respirations	26 breaths/min
Pulse	164 beats/min
Skin	Cool, pale, and clammy
Blood pressure	68/P
Oxygen saturation (Spo₂)	99% on 15 L/min
Pupils	PERRLA

- 7.** Did this patient require a second IV line?

Words of Wisdom

Take care when placing all potential patients in shock in a completely supine position. Although this may help temporarily increase perfusion in some patients in shock, it may have detrimental effects in others. In patients with chest injuries or difficulty breathing due to heart failure with cardiogenic shock (pump failure), this position may worsen symptoms. In patients with head injury, it may cause a detrimental increase in intracranial pressure. In these instances, consider elevating the head of the long backboard for patients being managed with spinal motion restriction to reduce pressure in the head and chest. As always, follow your local protocols or consult medical control.

Transport the patient and treat additional problems en route. If possible, consider rendezvousing with paramedics, and consider aeromedical transport. The Golden Hour refers to the first 60 minutes after injury, which is thought to be a critically important period. Because this time frame varies (more than an hour in some patients, less in others), the concept is often referred to as the Golden Period for the early resuscitation and treatment of severely injured trauma patients. This concept underscores the importance of rapid evaluation, stabilization, and transport. The goal of emergency medical services (EMS) is to limit on-scene time (time on scene until transport to hospital is started) to 10 minutes or less (the platinum 10).

If time allows, splint individual extremity fractures during transport. This minimizes pain, bleeding, and discomfort, all of which can aggravate shock. It also prevents the broken bone ends from further damaging adjacent soft tissue.

Do not give the patient anything by mouth, no matter how urgently you are asked. To relieve the intense thirst that often accompanies shock, give the patient a moistened piece of gauze to chew or suck. Never give a patient in shock an alcoholic drink or other depressant. A stimulant, such as coffee, also has no role in treating shock.

Finally, comfort, calm, and reassure the patient; speak calmly and reassuringly to a responsive patient throughout assessment, care, and transport.

The following list summarizes initial management for shock:

1. Manage the airway.
2. Administer supplemental oxygen to all patients with trauma, and to patients who are in respiratory distress or who have an SpO_2 of less than 94%.
3. Place the patient in a position of comfort or immobilize as indicated.
4. Obtain vital signs, including SpO_2 and glucose level.
5. Obtain IV/intraosseous access for medication or fluid bolus.
6. Maintain body heat.

Words of Wisdom

You are never wrong to treat for shock, and many patients will experience some degree of shock even if signs and symptoms are minimal. Consider whether or not you need to treat for shock for each patient you encounter.

TABLE 14-8 lists the general supportive measures for the major types of shock. Not every measure is used for every type of shock.

Special Populations

Treatment for a pediatric or geriatric patient in shock is no different than treatment of any other shock patient. However, remember that the very young and the very old compensate differently, so you must maintain a high index of suspicion and treat aggressively.

IV Therapy

IV lines are inserted for one of three purposes: (1) to provide a route for *immediate replacement* of fluid in patients who have already lost substantial volumes of fluid or blood, (2) to provide a route for *potential replacement* in patients who are at risk of losing substantial volumes of fluid or blood, and (3) to provide a route for the administration of medication. The IV fluid of choice is an isotonic crystalloid such as normal saline or lactated Ringer solution.

TABLE 14-8 Shock Treatment

Type of Shock	Treatment
Hypovolemic	Manage the airway Administer oxygen or assist ventilations as needed Control external bleeding Place supine Keep warm Transport promptly Gain IV access; provide fluid resuscitation en route
Cardiogenic	Place patient in a position of comfort Administer oxygen or assist ventilations as needed Transport promptly Gain IV access; administer fluid at a TKO rate
Obstructive	Dependent on cause: • Paramedic assist and/or rapid transport • Administer oxygen or assist ventilations as needed • Gain IV access as a medication route; administer fluid at a TKO rate
Septic	Transport promptly Administer high-flow oxygen or assist ventilations as needed Keep patient warm Gain IV access en route; administer fluid boluses to maintain radial pulses
Neurogenic	Manage the airway Spinal motion restriction if indicated Administer oxygen or assist ventilations as needed Preserve body heat Transport promptly Gain IV access; administer warmed IV fluids to maintain radial pulses
Anaphylactic	Manage the airway Administer oxygen or assist ventilations as needed Determine cause Administer epinephrine Gain IV access as a medication route; administer fluid at a TKO rate Transport promptly
Psychogenic (fainting)	Determine duration of unresponsiveness Position patient supine Record initial vital signs and mental status Suspect head injury if patient is confused or slow to respond Transport promptly

Abbreviations: IV, intravenous; TKO, to keep open

© Jones & Bartlett Learning.

All patients in hypovolemic shock need IV fluid replacement. In addition, IV access should be obtained in patients who are likely to develop hypovolemic shock due to loss of blood (internal or external) or fluid (vomiting, diarrhea, burns), or because of widespread vasodilation.

In case of need for emergency administration of medications, IV lines should also be inserted

TKO. When a patient has poor cardiac output (as in shock), blood is shunted away from the skin and skeletal muscles. Therefore, medications administered subcutaneously or intramuscularly are absorbed at a low and unpredictable rate. Administering a medication directly into the vein ensures that the desired dose of the drug reaches the circulation. Patients who need a vein TKO

include those at risk of cardiac arrest (it is easier to start the IV line before the arrest) and patients who may need parenteral medication (such as patients with seizures, diabetes, heart failure, or coma).

Establish IV access with at least one 18-gauge catheter, and administer an isotonic crystalloid solution to replace lost fluid. In the prehospital setting, use of larger catheters increases the risk of missing the IV line and does not add meaningfully to the ability to adequately administer small fluid boluses to address shock. The goal of volume replacement is to maintain perfusion without increasing hemorrhage or overloading a strained heart. Therefore, most protocols advise administration of IV fluid in boluses of 20 mL/kg up to 30 mL/kg in 250-mL increments until radial pulses return. The presence of radial pulses is thought to equate to a systolic blood pressure of approximately 80 to 90 mm Hg, which, in most people, is sufficient to perfuse the brain and other vital organs. However, studies have contested the belief that the simple presence of radial pulses, versus an actual blood pressure measurement, is sufficient in assuming organ perfusion.³ Raising blood pressure further may result in worsening cardiac failure or internal hemorrhage. Monitor the patient's response to IV therapy carefully and document any changes. Techniques for vascular access are discussed in Chapter 13, *Vascular Access and Medication Administration*.

If vital signs return to within normal limits or reach the desired status, reduce IV fluid administration to a TKO rate and reassess frequently, adjusting the flow as needed. If the patient's response to initial treatment shows no improvement or slow deterioration, there may be ongoing bleeding or fluid loss. Maintain the patient's blood pressure around 80–90 mm Hg systolic (maintain radial pulses), depending on local protocol, unless the patient also has sustained a brain injury, in which case hypotensive episodes are much more dangerous and associated with increased mortality. For patients with severe head injury, maintain systolic blood pressure at a minimum of 100 mm Hg.

Call early for paramedic intervention to administer vasopressors if needed. The vasodilation that accompanies distributive shock creates relative hypovolemia. Regardless of the cause, the problem is still a lack of fluid for the size of the container.

Words of Wisdom

Using larger-diameter and shorter-length catheters results in greater fluid flow. Choose a catheter that is size 18-gauge and which is no longer than 1 to 1.5 inches (2.5 to 3.8 cm). For maximum volume infusion, use a blood set or macrodrip set (10 to 15 drops/min) without a saline lock that restricts flow. Administer a bolus of 250 mL of an isotonic crystalloid solution. A second 18-gauge IV line may be established when it is safe to do so and time allows, but this is not necessary to initiate effective resuscitation.

Special Considerations in Fluid Resuscitation

For instances where increasing blood pressure may be detrimental to the patient, such as cardiogenic shock or massive internal bleeding, it may be necessary to administer only enough fluid to maintain radial pulses. Aggressive fluid therapy increases the workload on the heart, worsening cardiogenic shock and increasing internal bleeding by breaking up clots that are forming or increasing the pressure in the vessels.

Temperature control is vital to maintaining perfusion in children and infants. If fluid replacement is required and IV access cannot be obtained, consider using intraosseous infusion. Use a Broselow tape or other reference to remember normal vital signs by age. Infuse a 20-mL/kg bolus of a warmed isotonic crystalloid solution, considering a second infusion if there is no response to the first. While administering fluids, it is imperative to remember that a patient who has lost blood needs to replace RBCs. Carefully monitor patient status and treat conservatively in instances of uncontrolled hemorrhage. Use a continuous infusion to maintain adequate perfusion levels of critical organs en route to the hospital. A third infusion of 20 mL/kg may be considered after medical consultation.

Geriatric patients can present a challenge when providing IV therapy in instances of shock. Patients who have chronic hypertension may require a higher blood pressure to achieve the same level of end-organ perfusion than those who maintain a normal blood pressure. The geriatric patient may be in shock even with a systolic blood pressure of

above 100 mm Hg. Even modest amounts of fluid loss can be detrimental and result in shock in these patients because of a reduced circulating blood volume. Geriatric patients may also be less able to tolerate excessive fluids that may cause harmful electrolyte level alterations. Anemia may be yet another complication because aggressive fluid resuscitation may further reduce the relative concentrations of RBCs. For these patients, rapid transport is essential.

When you are treating obstetric patients, it is imperative to remember that there are two patients involved: the pregnant woman and the fetus. Because states of shock result in shunting of blood away from the fetus, the only way to maintain fetal perfusion is to aggressively treat the woman. Remember to place pregnant patients in a left lateral recumbent position, or tilt the backboard if the patient is immobilized, to increase perfusion. Provide fluid resuscitation to maintain radial pulses of the mother. The closer the maternal blood pressure is to normal, the better the perfusion of the fetus.

Assessment and Management of Specific Types of Shock

Treating Hypovolemic Shock

The emergency treatment of hypovolemic shock or hemorrhagic shock includes control of all obvious external bleeding. If bleeding is not controlled with direct pressure, consider use of a tourniquet. Tourniquet use is discussed in Chapter 27, *Bleeding*.

En route to the ED, establish at least one 18-gauge peripheral IV line using an over-the-needle catheter. Unless local medical policy favors a different resuscitation fluid, administer normal saline or lactated Ringer solution in an initial bolus of 250 mL. For guidance, refer to your local protocol. Then reassess the patient to see the effect of the intervention. Use warmed fluids when available.

Although you cannot control internal bleeding in the field, you must recognize its existence and provide aggressive general support. Secure and maintain an airway and provide respiratory support, including supplemental oxygen and, if needed, assisted ventilations. Administer oxygen as soon as you suspect shock, and continue providing it during transport; with too little circulating blood,

additional oxygen may be lifesaving. Be sure the patient does not aspirate blood or vomitus; keep suction at hand to clear the mouth and pharynx.

Words of Wisdom

Introducing large quantities of IV fluid may exacerbate internal bleeding. Give fluid judiciously and only enough to maintain palpable radial pulses. This equates to a systolic blood pressure of 80 to 90 mm Hg.

Do not give patients anything by mouth because they are likely to vomit, which could result in aspiration or airway obstruction. Keep patients at normal temperature, covering them with a blanket and warming the patient compartment of the ambulance; patients in hypovolemic shock are often unable to conserve body heat effectively and are easily chilled.

Monitor the patient's mental status, pulse rate, blood pressure, SpO₂, and, if required by your system, ET CO₂. (However, ET CO₂ does not provide additional actionable information on hypovolemic shock.) In a patient with substantial vasoconstriction, the blood pressure sounds may be difficult to hear, especially under field conditions. If you can feel a pulse over the femoral artery, but not over the radial artery, the systolic blood pressure is most likely between 70 and 80 mm Hg, although this is highly variable. The pulse oximetry and ET CO₂ findings will help you assess adequacy of oxygenation efforts. Monitoring ET CO₂, if available, can help you assess adequacy of ventilation and the potential need for ventilatory assistance.

Provide rapid transport to the closest, most appropriate facility. Consider calling for paramedic backup for advanced treatment or air transport when time is of the essence and the distance to definitive care is substantial.

Treating Cardiogenic Shock

The patient who is in cardiogenic shock as a result of a heart attack does not need excess fluid; this can be detrimental to the patient. The damaged heart muscle simply cannot generate the necessary power to pump blood throughout the circulatory system.

Keep in mind that chronic lung disease will aggravate cardiogenic shock. If the patient has chronic obstructive pulmonary disease and heart disease, oxygenation of the blood passing through the lungs is impaired. Because fluid is collecting in the lungs, this patient is often able to breathe better in a sitting or slightly reclining upright position. Usually, patients with cardiogenic shock do not have any injury, but they may be having chest pain as a result of ischemia from lack of perfusion. Before administering nitroglycerin to any patient with the potential for cardiogenic shock, be sure systolic blood pressure is greater than 90 mm Hg and consult with medical control for instructions. Assess the patient's blood pressure and gain IV access prior to nitroglycerin administration. Patients in cardiogenic shock often are already hypotensive. Administration of nitroglycerin will only exacerbate the problem and most likely have detrimental effects. Other signs of cardiogenic shock include a weak, irregular pulse; cyanosis about the lips and underneath the fingernails; anxiety; and nausea.

Treatment of cardiogenic shock should begin by placing the patient in a position of comfort and administering high-flow oxygen. Be ready to assist ventilations as necessary, and have suction nearby in case the patient vomits. Provide prompt transport to the ED. Gain IV access and administer fluid at a TKO rate. Remember also to approach a patient who has had a suspected heart attack with calm reassurance. Frequently checking for a pulse in an unresponsive patient is important to identify early whether an automated external defibrillator is needed.

Treating Obstructive Shock

As discussed previously, three of the most common examples of obstructive shock are pulmonary embolus, cardiac tamponade, and tension pneumothorax.

Increasing cardiac output should be the priority in treating cardiac tamponade. As the heart is being squeezed by the increasing pressure in the pericardium, the preload must be increased. Apply high-flow oxygen. Oxygen should never be withheld from a patient who needs it; however, you must weigh the need for positive-pressure ventilations against the possibility of decreased venous return to the chest and resultant decreased preload. The only

definitive treatment for cardiac tamponade is surgery or pericardiocentesis (inserting a needle into the pericardium and withdrawing the accumulated blood from the pericardial sac). Because neither of these is performed in the field, the only treatment available to prehospital providers is early recognition and rapid transport for definitive care.

In treating tension pneumothorax, high-flow oxygen via a nonrebreathing mask should be applied early to prevent hypoxia. Be cautious about providing positive-pressure ventilation to a patient with a tension pneumothorax because the increase of air will increase the pressure in the chest. Usually, the only action that can prevent eventual death from a tension pneumothorax is decompression of the injured side of the chest, relieving the pressure in the chest and allowing the heart to expand fully again. Needle chest decompression (needle thoracostomy) is a skill that paramedics are trained to perform. Rapid transport or paramedic backup, if available, is the key treatment available to AEMT providers. In patients with tension pneumothorax, gain IV access as a medication route and administer fluid at a TKO rate. Do not allow the process of gaining IV access to delay transporting the patient emergently to the trauma center. Tension pneumothorax is an extremely time-sensitive condition, and minutes matter in achieving decompression.

In treating pulmonary embolus in the prehospital setting, assess blood pressure; provide a fluid bolus of 250 mL of crystalloid solution; and recheck blood pressure. Multiple boluses may be indicated if you are unable to restore blood pressure to greater than 90 mm Hg systolic. The patient may breathe more comfortably in an upright or partially upright position. Definitive treatment involves anticoagulation to prevent progression, ventilatory and circulatory support, and occasionally thrombolytic therapy or clot retrieval. None of these is possible in the prehospital setting, so rapid transport to an appropriate facility is indicated.

Treating Septic Shock

The proper treatment of septic shock requires complex hospital management, including antibiotics. If you suspect that a patient has septic shock, you must use appropriate standard precautions and transport as promptly as possible. Use high-flow oxygen during transport. Ventilatory support may

be necessary to maintain adequate tidal volume. Use blankets to conserve body heat. Gain IV access en route and administer fluid boluses to maintain radial pulses.

Treating Neurogenic Shock

Shock that accompanies spinal cord injury is best treated by a combination of all known supportive measures. The patient who has sustained this kind of injury usually will require hospitalization for a long time. Emergency treatment must be directed at obtaining and maintaining a proper airway, providing spinal motion restriction to prevent progression of injury, assisting inadequate breathing as needed, conserving body heat, and providing the most effective circulation possible.

This patient usually is not losing blood. However, the capacity of the blood vessels has become substantially greater than the volume of blood these vessels contain. Supplemental oxygen will boost the concentration of oxygen in the blood. If respirations are weak or inadequate, provide assisted ventilations. Keep the patient as warm as possible with blankets, because the injury may have disabled the body's normal temperature controls. Gain IV access and administer warmed IV fluids to maintain radial pulses. Transport promptly.

Treating Anaphylactic Shock

The only truly effective prehospital treatment for a severe, acute allergic reaction is to administer epinephrine by way of subcutaneous or intramuscular injection. A patient who is aware of having a specific sensitivity may carry a bee-sting kit containing epinephrine (**FIGURE 14-8**). If the patient is unable to inject the medication, you may have to do so if you are allowed by local protocol. If the patient's signs and symptoms recur or the patient's condition deteriorates, you should repeat the injection after consulting with medical control. For more information on the emergency care for allergic reactions, see Chapter 22, *Immunologic Emergencies*.

Promptly transport the patient to the ED while providing all possible support, primarily supplemental oxygen and ventilatory assistance. Try to determine what agent caused the reaction (for example, a drug, an insect bite or sting, a food item) and how it was received (for example, by mouth, by inhalation, or by injection). The severity of allergic reactions can vary greatly, with symptoms ranging from mild itching to profound coma and rapid death. Keep in mind that a mild reaction may worsen suddenly or over time. Gain IV access as a medication route and administer fluid at a TKO rate. Consider requesting paramedic backup, if available.

Treating Psychogenic Shock

In an uncomplicated case of fainting, after the patient collapses and becomes supine, circulation to the brain is usually restored and, with it, a normal state of functioning. Remember that psychogenic shock can substantially worsen other types of shock. If the attack has caused the patient to fall, you must check for injuries, especially in older patients. If,

once alert, the patient is unable to walk without weakness, dizziness, or pain, you should suspect another problem, such as head injury. Transport the patient promptly.

Be sure to record your initial observations of vital signs and LOC. In addition, try to learn from bystanders whether the patient reported any problems before fainting and how long the patient was unresponsive.

YOU are the Provider SUMMARY

1. What is shock and how does it relate to perfusion?

Shock (hypoperfusion) describes a state of collapse and failure of the cardiovascular system. When the circulation of blood in the body becomes inadequate, the oxygen and nutrient needs in the cells cannot be met. In the early stages of shock, the body will attempt to maintain homeostasis (a balance of all systems of the body); however, as shock progresses, blood circulation slows and eventually ceases. This abnormal state of inadequate oxygen and nutrient delivery to the cells of the body causes organs, and then organ systems, to fail. If not treated promptly, shock can be fatal.

Perfusion is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal. Perfusion requires a working cardiovascular system. It also requires adequate oxygen exchange in the lungs, adequate nutrients in the form of glucose in the blood, and adequate waste removal, primarily through the lungs.

2. What factors does perfusion depend on?

Perfusion depends on cardiac output, SVR, and transport of oxygen. SVR is the resistance to blood flow within all blood vessels except the pulmonary vessels.

3. Which type of shock do you suspect this patient is experiencing?

This patient is most likely experiencing hypovolemic shock based on the lack of other findings. He does not have any signs or symptoms that would indicate cardiogenic shock, and has no history of spinal cord injury, infections, or anaphylaxis. Therefore, you must consider any patient presenting with signs and symptoms of shock without external injury to have probable internal bleeding or fluid loss, usually in the abdominal cavity.

4. Which stage of shock is this patient experiencing?

This patient is in decompensated shock, in which the circulating blood volume has decreased more

than 25%. The compensatory mechanisms are beginning to fail, and signs and symptoms are much more obvious. In this stage, cardiac output falls dramatically, resulting in further reductions in the blood pressure and cardiac function. The signs and symptoms become more obvious as blood is shunted to the brain, heart, and kidneys. At this point, vasoconstriction can have a disastrous effect if allowed to continue. Cells in the nonperfused tissues become hypoxic, resulting in anaerobic metabolism. Treatment at this stage sometimes results in recovery.

5. How much IV fluid should this patient receive?

This patient should receive fluid boluses of 20 mL/kg in 250-mL increments until systolic blood pressure exceeds 80 mm Hg. The presence of radial pulses equates roughly to a systolic blood pressure of 80 to 90 mm Hg, but this is variable and only a rough guide. Use actual cuff pressure measurements whenever possible. Increasing the blood pressure further may result in worsening internal hemorrhage. You should monitor the patient's response to IV therapy carefully and document any changes.

6. How should the patient be positioned on the stretcher for transport?

The patient should be placed supine on the stretcher. Placing the patient in this position will assist in increasing perfusion to the vital organs, thus increasing the patient's overall perfusion.

7. Did this patient require a second IV line?

This patient could benefit from a second IV line, if time allows. With the suspicion of a bleeding or perforated ulcer and the patient's presentation of decompensated shock, it is likely that this patient will further decompensate and need larger fluid boluses and, potentially, surgical intervention. You should always remember that it is easier to establish IV access while the patient is still relatively perfused, as opposed to waiting until the patient becomes profoundly hypotensive.

Narrative

EMS requested to respond to a patient reporting weakness and nausea with a "burning" epigastric pain. Patient states that he has not felt well over the past couple of days and his weakness and nausea became much worse this morning. He has a history of peptic ulcers and HTN. He has no drug allergies and medications are listed above. EMS found the patient lying supine in bed. He is alert and oriented but slow to respond. He is tachypneic with a respiratory rate of 25. Patient placed on a nonrebreathing mask at 15 L/min. His lungs are clear and he has a pulse oximetry reading of 98% on 15 L/min O₂ via NRM. His skin is cool and clammy with absent radial pulses. Carotid is rapid. He denies any trauma or physical activity. His abdomen is distended and tender to palpation. An 18-gauge IV catheter was established in the patient's right AC and a 250-mL bolus of NS was given. Patient placed supine and loaded into ambulance for rapid transport to the ED. A second bolus of 250-mL NS was delivered and an additional IV established with NS wide open while en route to the hospital. While en route the patient's LOC decreased and abdomen appears more distended. Airway continues to be open and clear. Respirations continue to be rapid. Weak radial pulses regained with fluid bolus, but rate continuing to increase. Patient rapidly transported to the ED without further incident.

End of report

Prep Kit**Ready to Review**

- Perfusion is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal. Perfusion requires an intact cardiovascular system and a functioning respiratory system.
- Blood is the vehicle for carrying oxygen and nutrients through the vessels to the capillary beds to tissue cells, where these supplies are exchanged for waste products.
- Blood flow through the capillary beds is regulated by the capillary sphincters that are

under the control of the autonomic nervous system. Regulation of blood flow occurs by vessel constriction or dilation, along with sphincter constriction or dilation.

- The *systolic* pressure is the peak arterial pressure, or pressure generated every time the heart contracts; the *diastolic* pressure is the pressure maintained within the arteries while the heart rests between heartbeats.
- Perfusion depends on cardiac output, SVR, and transport of oxygen. Cardiac output is the volume of blood that the heart can pump per minute. SVR is the resistance to blood flow within all blood vessels except the pulmonary vessels.
- Most types of shock (hypoperfusion) are caused by dysfunction in one or more parts of the perfusion triangle:
 - The pump (the heart)
 - The pipes, or container (blood vessels)
 - The content, or volume (blood)
- Shock (hypoperfusion) is the collapse and failure of the cardiovascular system, when blood circulation slows and eventually stops.
- The autonomic nervous system has a role in regulation of pulse rate, blood pressure, and respiratory rate. Activation of the sympathetic nervous system increases these; activation of the parasympathetic nervous system decreases these.
- The body has neural and hormonal mechanisms for regulating blood pressure, which is important to maintaining homeostasis. If perfusion decreases, baroreceptors sense the decreased flow and activate the vasomotor center, which oversees changes in the diameter of blood vessels, to begin constriction of the vessels and increase blood pressure. Chemoreceptors measure subtle shifts in the amounts of carbon dioxide in arterial blood and are important in regulating respiration.
- Failure of compensatory mechanisms to preserve perfusion results in decreases in preload and cardiac output. Myocardial blood supply and oxygenation decrease, reducing

myocardial perfusion. As cardiac output further decreases, coronary artery perfusion also decreases, resulting in myocardial ischemia.

- Multiple-organ dysfunction syndrome is a progressive condition in which several organ systems fail. This occurs when injury or infection triggers a massive systemic immune, inflammatory, and coagulation response.
- Suspect shock if the patient has substantial external or internal bleeding, multiple severe fractures, abdominal or chest injury, spinal injury, severe infection, major heart attack, or anaphylaxis.
- The various types of shock are hypovolemic, cardiogenic, septic, neurogenic, anaphylactic, and psychogenic.
- Signs of compensated shock include agitation, anxiety, or restlessness; a sense of impending doom; weak, rapid pulse; pale, cool, moist skin; shortness of breath; nausea and vomiting; and increased thirst. If there is any question on your part, treat for shock. It is never wrong to treat for shock.
- Notable signs of decompensated shock include altered mental status; hypotension; labored or irregular breathing; thready or absent pulses; ashen, mottled, or cyanotic skin; dilated pupils; diminished urine output; dry mucosa; and nausea and vomiting.
- Remember, by the time a decrease in blood pressure is detected, shock is usually in an advanced stage. Early recognition and treatment are crucial.
- Treating a pediatric or geriatric patient in shock is no different than treating any other shock patient.
- Treat all patients suspected to be in shock from any cause as follows:
 - Address life threats; control obvious external bleeding, then airway and breathing concerns.
 - If cardiac arrest is suspected, focus on high-quality chest compressions prior to airway and breathing.
 - Provide high-flow oxygen and, as needed, provide bag-mask-assisted ventilations.
 - Place the patient supine.

- Maintain normal body temperature with blankets.
- Provide prompt transport to the appropriate hospital.
- Gain IV access.
- Starting an IV line and administering fluids are part of treating a patient who is in shock.

Administer IV volume expanders (warmed if possible) to replace fluid loss. Isotonic crystalloids, such as normal saline or lactated Ringer solution, should be used (synthetic solutions may also be used). Call early for paramedic intervention to administer vasopressors if needed.

Vital Vocabulary

aerobic metabolism The metabolism that takes place in the presence of oxygen.

afterload The pressure in the aorta against which the left ventricle must pump blood; increasing this pressure can decrease cardiac output.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the principal product is lactic acid.

anaphylactic shock Severe shock caused by an allergic reaction; a severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

anaphylaxis An extreme, life-threatening, systemic allergic reaction to foreign protein or other substances, which may include shock and respiratory failure.

aneurysm A swelling or enlargement of part of an artery, resulting from weakening of the arterial wall.

angioedema Recurrent large areas of subcutaneous edema of sudden onset, often around the eyes and lips and usually disappearing within 24 hours.

autonomic nervous system The part of the nervous system that regulates functions that are not controlled consciously, but rather involuntarily, such as heart rate, blood pressure, digestion, and sweating.

baroreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in pressure in the heart or main arteries to help maintain homeostasis.

cardiac output The amount of blood pumped by the heart per minute; calculated by multiplying the stroke volume by the pulse rate per minute.

cardiac tamponade Compression of the heart caused by a buildup of blood or other fluid in the pericardial sac.

cardiogenic shock Shock caused by inadequate function of the heart, or pump failure; caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery; can be a severe complication of a large acute myocardial infarction, as well as other conditions.

chemoreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in chemical composition of the blood to help maintain homeostasis.

chronotropic effect Affecting the heart's rate of contraction.

compensated shock The early stage of shock, in which the body can still compensate for blood loss; also called nonprogressive shock.

cyanosis A blue-gray skin color that is caused by a reduced level of oxygen in the blood.

decompensated shock The late stage of shock when blood pressure is falling; also called progressive shock.

distributive shock The type of shock caused by widespread dilation of the resistance vessels (small arterioles), the capacitance vessels (small venules), or both.

dromotropic effect Affecting the heart's velocity of conduction.

edema The presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area.

Fick principle A principle stating that the movement and use of oxygen in the body is dependent on adequate concentration of inspired oxygen (FI_{O_2} [fraction of inspired oxygen]), appropriate movement of oxygen across the alveolar-capillary membrane into the arterial bloodstream, adequate number of red blood cells to carry the oxygen, proper tissue perfusion, and efficient off-loading of oxygen at the tissue level.

hemorrhagic shock A condition in which low blood volume due to massive internal or external bleeding results in inadequate perfusion.

homeostasis A tendency to constancy or stability in the body's internal environment; the balance of all systems of the body.

hypothermia A condition in which the internal body temperature falls below 95°F (35°C), usually as a result of prolonged exposure to cool or freezing temperatures.

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

inotropic effect Affecting the contractility of muscle tissue, especially cardiac muscle.

irreversible shock The final stage of shock, resulting in death.

mean arterial pressure (MAP) The average pressure against the arterial wall during a cardiac cycle; generally considered to be the same as blood pressure.

multiple-organ dysfunction syndrome (MODS) A progressive condition that occurs after severe illness or injury, usually characterized by combined failure of two or more organs or organ systems not affected by the patient's initial illness or injury, along with some clotting mechanisms.

myocardial contractility The ability of the heart muscle to contract.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, resulting in widespread

vasodilation and loss of sympathetic nervous system tone; seen in patients with spinal cord injuries.

nonhemorrhagic shock Shock that occurs as a result of fluid loss contained within the body, such as in dehydration, burn injury, crush injury, and anaphylaxis.

obstructive shock Shock that occurs when there is a block to blood flow in the heart or great vessels, causing an insufficient blood supply to the body's tissues.

orthostatic vital signs Vital signs assessed in two different patient positions (for example, in the supine and sitting or standing positions) to determine the degree of hypotension; also known as the tilt test.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

preload The precontraction pressure in the heart, which increases as the volume of blood builds up when returned to the heart (venous return); directly affects afterload.

psychogenic shock Shock caused by a sudden, temporary reduction in blood supply to the brain that causes fainting (syncope).

pulse pressure The difference between the systolic blood pressure and the diastolic blood pressure.

sensitization Development of a sensitivity to a substance that initially caused no allergic reaction.

septic shock The type of shock that occurs as a result of widespread infection, usually bacterial; untreated, the result is multiple-organ dysfunction syndrome and often death.

shock A condition in which the circulatory system fails to provide sufficient circulation to enable every body part to perform its function; also called hypoperfusion.

sphincters Circular muscles that surround and, by contracting, constrict a duct, tube, or opening. Examples are found within the rectum, bladder, and blood vessels.

syncope The temporary loss of consciousness and postural tone caused by diminished cerebral blood flow.

systemic vascular resistance (SVR) The resistance that blood must overcome to be able to move within the blood vessels; related to the

amount of dilation or constriction in the blood vessel.

tension pneumothorax An accumulation of air or gas in the pleural space that progressively collapses the lung with potentially fatal results.

Chapter 15

BLS Resuscitation

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Shock and Resuscitation

Applies fundamental knowledge to provide basic and selected advanced emergency care and

transportation based on assessment findings for a patient in shock, respiratory failure or arrest, cardiac failure or arrest, and postresuscitation management.

KNOWLEDGE OBJECTIVES

1. Explain the elements of basic life support (BLS), how it differs from advanced life support (ALS), and why BLS must be applied rapidly. (pp 805–806)
2. Explain the goals of cardiopulmonary resuscitation (CPR) and when it should be performed on a patient. (pp 806–807)
3. Explain the components of CPR, the six links in the American Heart Association (AHA) chain of survival, and how each one relates to maximizing patient survival. (pp 807–809)
4. Discuss guidelines for circumstances that require the use of an automated external defibrillator (AED) on both adult and pediatric patients experiencing cardiac arrest. (pp 810–812)
5. Explain four special situations related to the use of an AED. (pp 811–812)
6. Describe the proper way to position an adult patient to receive BLS care. (p 812)
7. Describe the purpose of external chest compressions. (p 813)
8. Describe the two techniques advanced emergency medical technicians (AEMTs) may use to open an adult patient's airway and the circumstances that would determine when to use each technique. (p 816)
9. Describe the recovery position and circumstances that would warrant its use as well as situations in which it would be contraindicated. (pp 817–818)
10. Describe the process of providing artificial ventilations to an adult patient, ways to avoid gastric distention, and modifications required for a patient with a stoma. (pp 818–819)
11. Explain the steps in providing one-rescuer adult CPR. (p 820)
12. Explain the steps in providing two-rescuer adult CPR, including the method for switching positions during the process. (pp 821–822)
13. Explain crew resource management and the roles of the team member and the team leader. (pp 822–824)
14. Summarize the steps of post-cardiac arrest care. (pp 824–825)
15. Describe the different mechanical devices that are available to assist emergency medical care providers in delivering improved circulatory efforts during CPR. (pp 825–828)
16. Describe the different possible causes of cardiopulmonary arrest in children. (p 828)
17. Explain pediatric BLS procedures and how they differ from BLS procedures used in an adult patient. (p 818)

18. Describe the ethical issues related to patient resuscitation, including examples of when not to start CPR on a patient. (pp 835–836)
19. Explain the various factors involved in the decision to stop CPR after it has been started on a patient. (pp 837–838)
20. Explain common causes of foreign body airway obstruction in both children and adults and how to distinguish mild or partial airway obstruction from complete airway obstruction. (pp 838–842)
21. Describe the different methods for removing a foreign body airway obstruction in an infant, child, and adult, including the procedure for a patient with an obstruction who becomes unresponsive. (pp 838–844)
22. Describe special resuscitation circumstances, such as opioid overdose or cardiac arrest in pregnancy. (pp 844–845)
23. Discuss how to provide grief support for a patient's family members and loved ones after resuscitation has ended. (pp 845–846)
24. Discuss the importance of frequent CPR training for AEMTs, as well as public education programs that teach compression-only CPR. (pp 846–847)

SKILLS OBJECTIVES

1. Demonstrate how to position an unresponsive adult for CPR. (p 838)
2. Demonstrate how to check for a pulse at the carotid artery in an unresponsive child or adult. (p 812)
3. Demonstrate how to perform external chest compressions on an adult. (p 814, Skill Drill 15-1)
4. Demonstrate how to perform a head tilt–chin lift maneuver on an adult. (p 816)
5. Demonstrate how to perform a jaw-thrust maneuver on an adult. (pp 816–817)
6. Demonstrate how to place a patient in the recovery position. (pp 817–818)
7. Demonstrate how to perform artificial ventilations in an adult. (pp 818–820)
8. Demonstrate how to perform one-rescuer adult CPR. (p 820, Skill Drill 15-2)
9. Demonstrate how to perform two-rescuer adult CPR. (pp 821–822, Skill Drill 15-3)
10. Demonstrate the use of mechanical devices that assist emergency responders in delivering improved circulatory efforts during CPR. (pp 825–828)
11. Demonstrate how to check for a pulse at the brachial artery in an unresponsive infant. (p 830)
12. Demonstrate how to perform external chest compressions on an infant. (p 831, Skill Drill 15-4)
13. Demonstrate how to perform CPR on a child who is between 1 year of age and the onset of puberty. (p 832, Skill Drill 15-5)
14. Demonstrate how to perform a head tilt–chin lift maneuver on a pediatric patient. (p 833)
15. Demonstrate how to perform a jaw-thrust maneuver on a pediatric patient. (p 833)
16. Demonstrate how to perform rescue breathing on a child. (pp 833–834)
17. Demonstrate how to perform rescue breathing on an infant. (p 834)
18. Demonstrate how to remove a foreign body airway obstruction in a responsive adult patient using abdominal thrusts (Heimlich maneuver). (pp 839–840)
19. Demonstrate how to remove a foreign body airway obstruction in a responsive pregnant patient or patient with obesity using chest thrusts. (pp 839–840)
20. Demonstrate how to remove a foreign body airway obstruction in a responsive child older than 1 year using abdominal thrusts (Heimlich maneuver). (pp 839–840)
21. Demonstrate how to remove a foreign body airway obstruction in an unresponsive child. (p 843, Skill Drill 15-6)
22. Demonstrate how to remove a foreign body airway obstruction in an infant. (pp 842–844)

Introduction

The principles of basic life support (BLS), or cardiopulmonary resuscitation (CPR), were introduced in 1960. Since then, the specific techniques for the management of cardiac arrest and the *Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care* have been reviewed and revised every 5 years by the American Heart Association (AHA), in concert with the International Liaison Committee on Resuscitation (ILCOR). However, in 2015, it was determined a 5-year cycle is insufficient to keep pace with the rapidly evolving research in resuscitation science, so it is planned for the guidelines to be updated on a more regular basis. The goal is to produce the best recommendations possible given the available scientific evidence. The updated guidelines are published in peer-reviewed journals: *Circulation* in the United States and *Resuscitation* in Europe. The most recent review conducted by ILCOR occurred as a result of a rigorous and systematic review of the newest scientific evidence surrounding the treatment of cardiac arrest and the provision of emergency and cardiac care, using validated, transparent, and scientifically rigorous methodology to produce the best recommendations possible given the available evidence.

This chapter begins with a definition and general discussion of BLS. It then reviews methods for opening and maintaining a patent (open) airway, providing artificial ventilation to a person who is not breathing, providing artificial circulation to a person with no pulse, removing a foreign body airway obstruction, and postresuscitation care for those with a return of spontaneous circulation. Each of these topics is followed by a review of the changes in technique that are necessary to treat infants and children. Chapter 2, *Workforce Safety*

and *Wellness*, discusses the methods of preventing the transmission of infectious diseases during CPR. Chapter 7, *The Human Body*, discusses the anatomy and physiology of the respiratory and cardiovascular systems.

Working as a team during an emergency is crucial to give the patient the best chance for a successful outcome. Rapid initiation of uninterrupted chest compressions offers the best chance of survival for victims of cardiac arrest while awaiting **advanced life support (ALS)** intervention. Effective teamwork with good communication increases the potential for a positive outcome.

Safety

Although your chances of contracting a disease during CPR training or actual CPR on a patient are very low, both common sense and Occupational Safety and Health Administration (OSHA) guidelines demand you take reasonable precautions to prevent unnecessary exposure to an infectious disease. By taking standard precautions, you can significantly reduce your risk of being exposed to an infectious disease.

Elements of BLS

Basic life support (BLS) is noninvasive, emergency life-saving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest. BLS follows a specific sequence for adults and for infants and children. This care focuses on the ABCDEs: Airway (obstruction), Breathing (respiratory arrest), Circulation (cardiac arrest or severe bleeding), Disability (brief neurologic evaluation), and Exposure (adequate exposure

YOU are the Provider

Part 1

It is a hot summer day. At 1445 hours, you and your partner respond to the local farmer's market for an unresponsive patient sitting in a pickup truck. While you are en route to the scene, dispatch informs you that bystander CPR is in progress. Your response time is less than 5 minutes.

1. What should you immediately do on receiving this update from dispatch?
2. What should be your initial actions on arriving at this scene?

of each area being examined). If the patient is in cardiac arrest, then a CABDE sequence (Compressions, Airway, Breathing, Disability, and Exposure) is used because chest compressions are essential and must be started as quickly as possible (**FIGURE 15-1**). Ideally, only seconds should pass between the time you recognize that a patient needs BLS and the start of treatment. Remember, brain cells die every second that they are deprived of oxygen. Permanent brain damage is possible after only 4 to 6 minutes without oxygen (**FIGURE 15-2**).

If a patient is not breathing adequately or at all, then you may be able to restore normal breathing simply by opening the airway. However, if the patient has no pulse, then you must combine artificial ventilation with artificial circulation (chest compressions). If breathing stops before the heart

FIGURE 15-1 Chest compressions are essential and must be started as quickly as possible.

FIGURE 15-2 Time is critical for patients who are not breathing. If the brain is deprived of oxygen for 4 to 6 minutes, brain damage is possible.

© Jones & Bartlett Learning.

stops, then the patient may have enough oxygen in the lungs to stay alive for several minutes. But when cardiac arrest occurs first, the heart and brain stop receiving oxygen immediately.

Cardiopulmonary resuscitation (CPR) is used to establish circulation and artificial ventilation in a patient who is not breathing and has no pulse. The steps for CPR include the following:

1. Open the airway with the jaw-thrust or head tilt–chin lift maneuver.
2. Perform 30 high-quality compressions to a depth of 2 to 2.4 inches (5 to 6 cm) in an adult at the rate of 100 to 120 per minute to circulate blood to the vital organs.
3. Provide rescue breaths (via mouth-to-mask ventilation or bag-mask ventilation). Administer 2 breaths, each over 1 second, while visualizing for chest rise.

The goal of CPR is to help restore spontaneous breathing and circulation; however, defibrillation and advanced interventions (ie, medication therapy) are often necessary to achieve this outcome. For CPR to be effective, you must be able to quickly identify a patient who is in respiratory and/or cardiac arrest and immediately begin BLS measures (**FIGURE 15-3**).

BLS differs from ALS, which involves advanced life-saving procedures, such as cardiac monitoring, administration of intravenous (IV) or intraosseous (IO) fluids and medications, and the use of advanced airway adjuncts. However, when done

FIGURE 15-3 You must quickly identify patients in respiratory and/or cardiac arrest so basic life support measures can begin immediately.

FIGURE 15-4 The six links of the chain of survival.

© Jones & Bartlett Learning. Data from American Heart Association.

correctly, BLS care can maintain life for a short time until ALS measures can be started. In some cases, such as choking, near drowning, or lightning injuries, early BLS measures may be all that is needed to restore a patient's pulse and breathing. Of course, these patients still require transport to the emergency department (ED) for evaluation.

The BLS measures are only as effective as the person who is performing them. Your skills may be good immediately after training, but as time goes on, skills will deteriorate unless you practice them regularly.

To survive cardiac arrest, effective CPR at an adequate rate and depth with minimal interruptions is essential until defibrillation can be administered. Therefore, the BLS care you provide as an advanced emergency medical technician (AEMT) is an extremely critical factor in the patient's chance for survival and, in many ways, is as important as the ALS care you will provide.

Words of Wisdom

Remember to push hard and push fast! Some BLS classes use music to set the beat while teaching CPR. Songs such as the 1970s disco classic "Staying Alive" offer an enjoyable learning experience and just may serve as a reminder for a provider who is actually performing chest compressions.

The Components of CPR

According to the AHA, 70% of out-of-hospital cardiac arrests occur in the home.¹ Few patients who experience cardiac arrest in the prehospital

environment survive unless a rapid sequence of events takes place. The AHA has determined an ideal sequence of events, termed the chain of survival, that if taken can improve the chance of successful resuscitation of a patient who experiences sudden cardiac arrest (**FIGURE 15-4**). A successful resuscitation is defined not only by the **return of spontaneous circulation (ROSC)**, but also the survival of the patient to hospital discharge. The six links in the chain of survival are as follows:²

1. **Recognition and activation of the emergency response system.** The first step in the chain of survival requires public education and awareness. Laypeople must learn to recognize the early warning signs of a cardiac emergency and immediately activate emergency medical services (EMS) by calling 9-1-1. This step ensures emergency responders are dispatched to the scene quickly, thus allowing the other links of the chain to be more effective. In modern EMS systems, the 9-1-1 dispatcher can provide prearrival instructions and direct the caller to provide CPR if needed.
2. **Immediate, high-quality CPR.** The initiation of immediate CPR by a bystander is essential for successful resuscitation of a person in cardiac arrest. CPR will keep blood, and thereby oxygen, flowing to the vital organs to keep the patient alive until the other components of the chain are available. The more people trained in CPR in the community, the better the chances of CPR being administered quickly to a person in cardiac arrest. Immediate, high-quality CPR markedly increases the patient's chance of survival, whereas a delay in CPR leads to poor patient outcomes. The lay public as well

as emergency responders should all be trained in CPR. Unfortunately, many bystanders are hesitant to perform CPR on a stranger for fear of contracting a disease from mouth-to-mouth breathing, or out of fear of liability. A perception that bystander CPR involves both mouth-to-mouth breathing and chest compressions persists. Laypeople should be educated in performing compression-only (hands-only) CPR.

For chest compressions to be most effective, they must be given hard and fast. The AHA recommends compressions be started as quickly as possible after onset of cardiac arrest. Compressions should be between 2 and 2.4 inches in depth (5 to 6 cm) and given at a rate of 100 to 120 per minute. The chest should completely recoil between each compression to maximize blood return to the heart. The rescuer should never lean on the chest between compressions. Interruptions between compressions for any reason should be minimized (less than 10 seconds).

3. **Rapid defibrillation.** Provided that immediate, high-quality CPR with minimal interruption is performed, early defibrillation offers the best opportunity to achieve a successful patient outcome. Automated external defibrillators (AEDs) have become readily available in many schools, fitness clubs, concert venues, sports arenas, government buildings, and other mass gathering places. The simple design of the AED makes it easy for emergency medical providers and laypeople to use with very little training.
4. **Basic and advanced EMS.** This link in the chain describes care provided by AEMTs and other ALS providers before the patient arrives at the ED. Such care includes continuing high-quality CPR, basic airway management (ie, oral airway insertion, bag-mask ventilation), advanced airway management (ie, endotracheal [ET] intubation or use of supraglottic airway devices), manual defibrillation, vascular access, transcutaneous pacing, and medication administration. In addition to the care you provide in the prehospital setting, be familiar with the cardiac resuscitation centers in your service area. Your agency should implement a process to ensure early notification and transport to the appropriate receiving facility.
5. **ALS and postarrest care.** After your team delivers the patient to the ED, further cardiopulmonary and neurologic support is provided to improve the patient's recovery when indicated. This support can include additional medication therapy to support blood pressure, targeted temperature management (ie, therapeutic hypothermia), maintenance of blood glucose levels, cardiac catheterization, an electroencephalogram to detect seizure activity, and admission to the intensive care unit for critical care management.
6. **Recovery.** After cardiac arrest, survivors can have physical, cognitive, and emotional challenges and may need ongoing therapies and interventions.

If any one of the links in the chain is absent or not maintained, the patient is more likely to die. For example, few patients survive cardiac arrest if CPR is not administered within the first few minutes. Likewise, if the time from cardiac arrest to defibrillation is more than 10 minutes, the chance of survival is minimal. The patient's best chance of survival occurs when all links in the chain are continuously maintained.

FIGURE 15-5 shows an algorithm with the components of providing advanced cardiac life support to a patient in cardiac arrest, including defibrillation, CPR, IV/IO access, and postcardiac care. The rest of this chapter will discuss these components in depth.

As soon as resources permit, IV or IO access should be established as a fluid and medication route. A patient may be hypoglycemic, and administration of dextrose (D₅₀W [50% dextrose in water]) may help with the ROSC. Use the Hs & Ts mnemonic described by the AHA to determine possible reversible causes of the cardiac arrest, many of which are treatable on an AEMT level:³

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypo/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

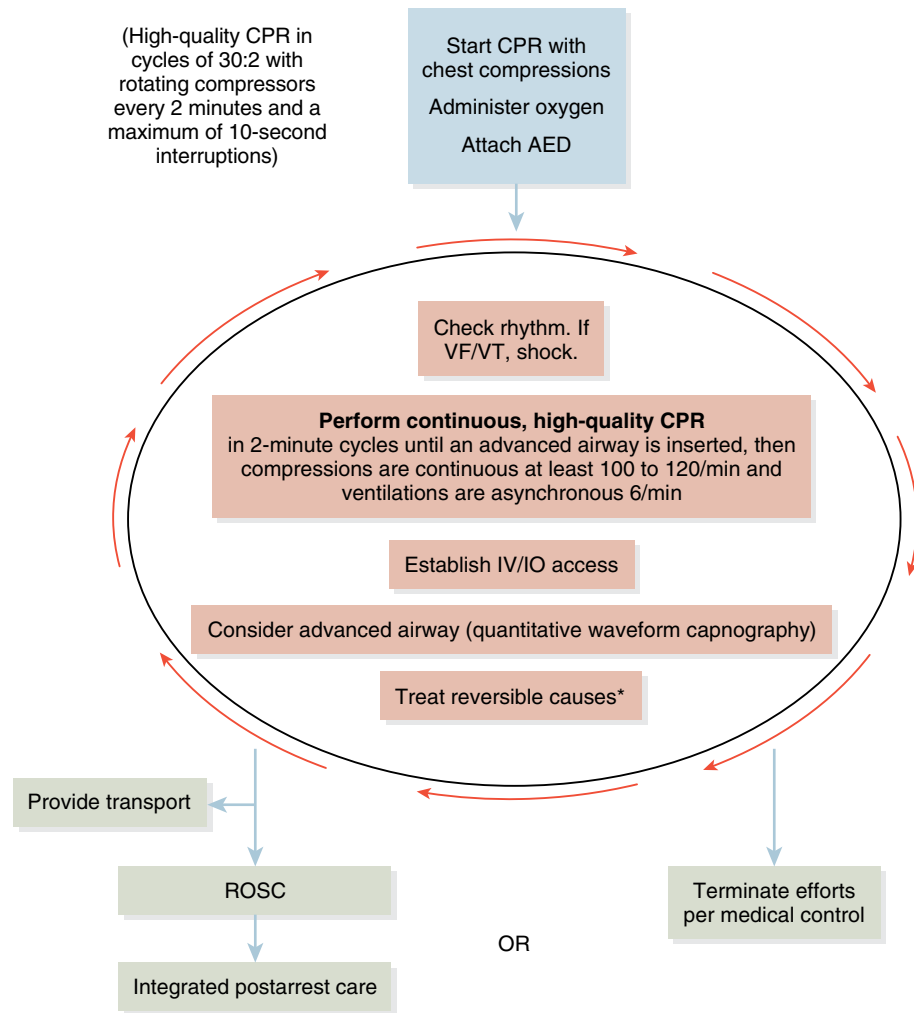

FIGURE 15-5 Algorithm for providing advanced cardiac life support. *Reversible causes in adults that can be treated by AEMTs include Hs and Ts: hypovolemia, hypoxia, hydrogen ion (acidosis), hypo/hyperkalemia, hypothermia, tension pneumothorax, tamponade (cardiac), toxins (naloxone can be administered), and pulmonary or coronary thrombosis. In pediatric patients, hypoglycemia is also a reversible cause.

© Jones & Bartlett Learning.

Words of Wisdom

If you anticipate the need for additional assistance, alert dispatch *immediately!* Do not wait until you begin performing CPR to avoid having to stop to use the radio.

Assessing the Need for BLS

As always, begin by surveying the scene. Is the scene safe? How many patients are present? What is your general impression of the patient? Are bystanders

present who may have additional information? What is the mechanism of injury or nature of illness? Do you suspect trauma? Do you need additional assistance? If you were dispatched to the scene, then does the dispatch information match what you see?

Because of the urgent need to start CPR in a pulseless, apneic patient, you must complete a primary survey as soon as possible and begin CPR, starting with chest compressions. The first step is to determine unresponsiveness. Gently tap the patient on the shoulder and shout, “Are you okay?” (FIGURE 15-6). If the patient does not respond to verbal or physical stimuli, the patient is considered

FIGURE 15-6 Assess an unresponsive patient by first attempting to rouse the person by tapping on the shoulder.

© Jones & Bartlett Learning, Courtesy of MIEMSS.

unresponsive. A patient who is responsive does not need CPR. Continue your assessment by simultaneously checking for breathing and a pulse; this step should take no more than 10 seconds. If the patient is in cardiac arrest, then begin CPR immediately.

If you suspect the presence of a cervical spine injury, then take precautions to protect the spinal cord from further injury as you perform CPR. If there is even a remote possibility of this type of injury, then begin taking appropriate actions during the primary survey.

You may encounter a cardiac arrest patient while off duty. If you are alone and off duty, use your mobile phone to call 9-1-1. If you are alone and do not have a mobile phone, leave the patient to call 9-1-1 and then return to begin CPR. If you choose to intervene while off duty, you must continue to provide competent care until an equal or higher medical authority assumes care of the patient. Recall from Chapter 3, *Medical, Legal, and Ethical Issues*, that you must be familiar with the laws and policies that apply in your service area regarding your duty to act.

Basic Principles of BLS

The basic principles of BLS are the same for infants, children, and adults. For the purposes of BLS, anyone younger than 1 year is considered an infant. A child is between 1 year of age and the onset of puberty (approximately 12 to 14 years of age), as signified by breast development in girls and underarm, chest, and facial hair in boys. Adulthood is from the onset of puberty and older. Children vary in size. Some small children may best be treated as infants, some larger children as adults. There are two basic differences in providing CPR for infants, children,

and adults. The first is that the emergencies in which infants and children require CPR usually have different underlying causes. The second is that there are anatomic differences in adults, children, and infants, such as smaller airways in infants and children than in adults.

Although cardiac arrest in adults usually occurs before respiratory arrest, the reverse is true in infants and children. In most cases, cardiac arrest in children results from respiratory arrest. If untreated, respiratory arrest will quickly lead to cardiac arrest and death. Respiratory arrest in infants and children has a variety of causes, including aspiration of foreign bodies into the airway, such as parts of hot dogs, peanuts, candy, or small toys; airway infections, such as croup and epiglottitis; near-drowning incidents or electrocution; and sudden unexpected infant death.⁴

Automated External Defibrillation

Most prehospital cardiac arrests occur as the result of a sudden cardiac rhythm disturbance (dysrhythmia), such as ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). The normal heart rhythm is known as a sinus rhythm and originates in the sinoatrial (SA) node. VF is the disorganized quivering of the ventricles generated by ectopic foci (electrical activity originating from a site other than the SA node) resulting in no forward blood flow and a state of cardiac arrest. VT is a rapid contraction of the ventricles that does not allow for normal filling of the heart. As mentioned previously, according to the AHA, early defibrillation is the link in the chain of survival that is most likely to improve survival rates. The likelihood of survival decreases rapidly over time as long as VF or pulseless VT persists.

Words of Wisdom

The heart is the only muscle that has the property of automaticity—the ability to generate its own electrical impulses. Ectopic means outside of the normal area (think of an ectopic pregnancy—the embryo is implanted somewhere other than inside the uterus). Ectopic electrical activity in the heart is generated from cells other than the SA node (the normal area for initiation of electrical impulses) and causes cardiac dysrhythmias.

When a patient is in cardiac arrest, begin CPR, starting with high-quality chest compressions, and apply an AED as soon as it is available. If indicated, defibrillate immediately. Chapter 18, *Cardiovascular Emergencies*, covers AED use in detail.

Words of Wisdom

If you witness a cardiac arrest and an AED is available, immediately apply and activate it. Next, begin CPR. However, if you did not witness the patient's cardiac arrest or if an AED is unavailable, then perform CPR and apply the AED as soon as it is available. If two or more rescuers are present, one rescuer should begin chest compressions while the other prepares to defibrillate using the AED.

AED Use in Children

AEDs can safely be used in children using the pediatric-size pads and a dose-attenuating system (energy reducer). However, if these items are unavailable, use adult-size AED pads. Apply the AED to infants or children after the first five cycles of CPR have been completed. Recall that cardiac arrest in children is usually the result of respiratory failure; therefore, oxygenation and ventilation are vitally important. After the first five cycles of CPR, use the AED to deliver shocks in the same manner as with an adult patient.

If the patient is an infant (between 1 month and 1 year of age) and paramedics are available, then a manual defibrillator is preferred. As with any cardiac arrest situation, immediately call for paramedic backup. If paramedic backup with a manual defibrillator is unavailable, then an AED equipped with pediatric-size pads and a dose attenuator is preferred over adult-size pads. If neither is available, then use an AED with adult-size pads.

Words of Wisdom

Never apply an AED to a patient with a pulse. The AED is designed to detect VF and VT, but cannot detect the presence of a pulse. Some patients with VT still have a pulse and are treated differently from those in cardiac arrest. Defibrillating a patient with a pulse will most likely result in cardiac arrest.

If you use adult-size AED pads on an infant or small child, never cut the pads to adjust the size. Instead, use the anterior-posterior placement, following the manufacturer's recommendation.

Special AED Situations

It is essential to ensure your safety, the safety of others at the scene, and the patient. As such, keep the following factors in mind when using an AED.

Pacemakers and Implanted Defibrillators

You may encounter a patient who has an automated implanted cardioverter-defibrillator (AICD) or pacemaker. These devices are used in patients who are at a high risk for certain cardiac dysrhythmias and cardiac arrest. It is easy to recognize AICDs or pacemakers because they create a hard lump beneath the skin, usually on the upper left side of the chest (just below the clavicle). If the AED pads are placed directly over the device, then the effectiveness of the shock delivered by the AED may be blocked, and the shock could potentially damage the implanted device. Therefore, if you identify an AICD or pacemaker, then place the AED pads at least 1 inch (2.5 cm) away from the device.

Occasionally, the implanted device will deliver shocks to the patient. If you observe the patient's muscles twitching as if a shock had just been administered, then continue CPR and wait 30 to 60 seconds before delivering a shock from the AED.

Special Populations

If you encounter an infant or small child in cardiac arrest who has an existing cardiac condition, then assess the chest and abdomen carefully for the presence of an implanted device. Small infants and children do not have sufficient musculature in the chest to support the device, so it is typically implanted in the abdomen. By the time the child reaches school age, it has generally been moved to the upper left chest under the clavicle.

Water

Water conducts electricity. Therefore, the AED should not be used in water. If the patient's chest is wet, the electrical current may move across the skin

rather than between the pads to the patient's heart. If the patient is submerged in water, pull them out of the water and quickly dry the skin before attaching the AED pads. Do not delay CPR to dry the patient thoroughly; instead, quickly wipe off as much moisture as possible from the chest. If the patient is lying in a small puddle of water or in the snow, the AED can be used, but again, the patient's chest should be quickly dried as much as possible.

Hair

Occasionally, you will encounter a patient with enough chest hair to prevent the AED pads from adhering properly. The pads must be in direct contact with the chest to effectively defibrillate the patient. You may receive a “check electrodes” or “check pads” error message from the AED when you attempt to analyze if the pads are not adhering to the chest or if the cable is not properly connected to the AED. EMS providers generally carry small razors for removing hair. The quickest way to remove hair is to press the AED pads firmly against the chest in the appropriate area and then quickly pull them off, taking the hair with the pad. Take a new set of pads and place over the areas where the hair has been removed. Ensure you have at least two sets of AED pads before using the first set of pads to remove hair.

Transdermal Medication Patches

You may encounter a patient who is receiving medication through a transdermal medication patch, such as nitroglycerin, nicotine, hormones, or various pain medications. The patch could reduce the flow of the electrical current from the AED to the heart and may burn the skin. If the medication patch interferes with AED pad placement, remove the patch with your gloved hands and wipe the skin with gauze to remove any residue prior to attaching the AED pad. Because the medication is absorbed through the skin, it will be absorbed through your skin if you are exposed to it. Patches should be removed as soon as possible, but should not take precedence over chest compressions. The medication delivered through the patch may be instrumental in the cause of the cardiac arrest. For example, nitroglycerin is a potent vasodilator that may cause hypotension and narcotic patches are a common source of overdoses.

FIGURE 15-7 Ensure the patient is in a supine position. Protect the patient's neck in case a spinal injury is present, and move the person as a unit, without twisting.

Courtesy of Rhonda Hunt.

Positioning the Patient

For CPR to be effective, the patient must be lying supine on a firm, flat surface, with enough clear space around the patient for at least two rescuers to perform CPR and use the AED. If the patient is crumpled up or lying face down (prone), you need to move the patient to a supine position with attention to cervical spine control if a potential injury is suspected (**FIGURE 15-7**). If the patient is found in a bed, then move them to the floor. You cannot effectively perform chest compressions on a soft or pliable surface.

If possible, log roll the patient onto a long backboard while positioning them for CPR. A backboard will provide support for CPR and offer an easy medium for moving the patient as a unit.

Check for Breathing and a Pulse

After you determine a patient is unresponsive, quickly check for breathing and a pulse. These assessments can occur simultaneously and should take no longer than 10 seconds in total.

Visualize the chest for signs of breathing while palpating for a carotid pulse. Feel for the carotid artery by locating the larynx at the front of the neck and then sliding two fingers toward one side (the

FIGURE 15-8 Feel for the carotid artery by locating the larynx, then slide your index and middle fingers toward one side. You can feel the pulse in the groove between the larynx and sternocleidomastoid muscle.

© Jones & Bartlett Learning.

side closest to you). The pulse is felt in the groove between the larynx and sternocleidomastoid muscle, with the pads of the index and middle fingers held side by side (**FIGURE 15-8**). Light pressure is sufficient to palpate the pulse.

Provide External Chest Compressions

If the patient is not breathing (or is breathing only slowly or occasionally, known as agonal gasps) and does not have a pulse, then begin CPR, starting with chest compressions. It is critical to perform compressions properly. Chest compressions are administered by applying rhythmic pressure and relaxation to the lower half of the sternum. The heart is located slightly to the left of the middle of the chest between the sternum and the spine (**FIGURE 15-9**). Compressions squeeze the heart, thereby acting as a pump to circulate blood. Allow the chest to completely recoil between compressions, which enhances blood return to the heart. Do not lean on the chest between compressions. When artificial ventilation is provided, the blood that is circulated through the lungs during chest compressions is likely to receive adequate oxygen to maintain tissue perfusion. However, even when external chest compressions are performed properly, they circulate only one-third of the blood that is normally pumped by the heart.

FIGURE 15-9 The heart lies slightly to the left of the middle of the chest between the sternum and spine.

© Jones & Bartlett Learning.

Proper Hand Position and Compression Technique

With the adult patient, correct hand position is established by placing the heel of one hand on the sternum in the center of the chest (lower half of the sternum). Your technique may be improved or made more comfortable if you interlock the fingers of your lower hand with the fingers of your upper hand.

To perform chest compressions, follow the steps in **SKILL DRILL 15-1**.

Words of Wisdom

An alternate technique for chest compressions may be helpful for those with arthritis or other joint conditions. Place the first hand in the proper position on the sternum and use the second hand to grasp the wrist of the first hand to provide support during the compressions.

Complications from chest compressions are rare but can include fractured ribs, a lacerated liver, and a fractured sternum. Although these injuries cannot be entirely avoided, you can minimize the chance that they will occur if you use good technique and proper hand placement.

Skill Drill 15-1 Performing Chest Compressions

Step 1

Take standard precautions. Place the heel of one hand on the center of the chest over the lower half of the sternum.

Step 2

Place the heel of your other hand over the first hand.

Step 3

With your arms straight, lock your elbows and position your shoulders directly over your hands, so the thrust of each compression is straight down on the sternum. Do not rock forward on the ribs during compressions. Depress the sternum at a rate of 100 to 120 compressions per minute and to a depth of 2 to 2.4 inches (5 to 6 cm) using a downward movement. Allow the chest to return to its normal position; do not lean on the patient's chest between compressions. Compression and relaxation should be of equal duration.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Words of Wisdom

If you hear a popping or crunching noise, or if you feel crepitus during chest compressions, then stop long enough to reassess your hand position. You may fracture the patient's ribs if your hands are to the left or right of the sternum. If your hand placement is correct, then continue with compressions.

Your motions must be smooth, rhythmic, and uninterrupted (**FIGURE 15-10A**). Short, jabbing compressions are not effective in producing

artificial blood flow. Do not remove the heel of your hand from the patient's chest during relaxation, but ensure you completely release pressure on the sternum so it can return to its normal resting position between compressions (**FIGURE 15-10B**).

It is more dangerous to compress the chest too lightly than it is to compress too forcefully. Compressing hard can lead to fatigue, and as you become tired, your compressions will become shallower. Therefore, it is critical to push hard and push fast and switch compressors (the person providing chest compressions) every 2 minutes—even if the compressor does not feel tired.

FIGURE 15-10 A. Compression and relaxation should be rhythmic and of equal duration (a 1:1 ratio). **B.** Pressure on the sternum must be released so the sternum can return to its normal resting position between compressions.

© Jones & Bartlett Learning.

Special Populations

Proper hand position and depth of compression, which are always important, take on added priority in geriatric patients, who are likely to have brittle bones and chest cartilage. There is no guarantee against causing injury to these tissues, and you must compress adequately to provide adequate perfusion of vital organs. Pay particular attention to your compression technique and hand placement, to help reduce avoidable injuries.

Words of Wisdom

Chest compressions create blood flow to the heart through filling of the coronary arteries. Every time compressions are stopped, blood flow—and, thus, perfusion—to the heart (and brain) drops to zero. It takes 5 to 10 compressions to reestablish effective blood flow to the heart after chest compressions are resumed. Avoid frequent or prolonged interruptions in chest compressions, which lead to poor patient outcomes.

Words of Wisdom

When performing chest compressions on an adult, compress the chest to a depth of at least 2 inches (5 cm), but not more than 2.4 inches (6 cm). It is difficult to achieve such a precise depth without the use of a monitoring device that provides immediate feedback (**FIGURE 15-11**). If such a device is available to you, then use it.

FIGURE 15-11 Cardiopulmonary resuscitation feedback devices help ensure a consistent rate and depth of compressions.

Opening the Airway and Providing Artificial Ventilation

Opening the Airway in Adults

Without an open airway, rescue breathing will not be effective. The two techniques for opening the airway in adults are the head tilt–chin lift maneuver and the jaw-thrust maneuver. These manual maneuvers are designed to bring the tongue forward and off the back of the throat. The **head tilt–chin lift maneuver** is effective for opening the airway in most patients when there is no indication of a spinal injury. **FIGURE 15-12** reviews how to perform the head tilt–chin lift maneuver in an adult. See Chapter 11, *Airway Management*, for more information.

In patients who have not sustained trauma, this simple maneuver is sometimes all that is required for the patient to resume breathing (**FIGURE 15-13**). If the patient has any foreign material or vomitus in the mouth, then quickly remove it. Liquids may be removed with a suction device, and solid materials may be removed by using your hooked index finger. If suction is not readily available, roll the patient to the side to remove foreign materials.

FIGURE 15-12 To perform the head tilt–chin lift maneuver, place one hand on the patient's forehead and apply firm backward pressure with your palm to tilt the head back. Next, place the tips of the index and middle fingers of your other hand under the lower jaw near the bony part of the chin. Lift the chin upward, bringing the entire lower jaw with it, helping to tilt the head back.

© Jones & Bartlett Learning.

Special Populations

When caring for older patients who wear dentures, the head tilt–chin lift maneuver has the added advantage of holding loose dentures in place, which makes obstruction by the lips less likely. Performing ventilation is much easier when dentures are in place. However, remove dentures that do not stay in place. Partial dentures (plates) may become loose as a result of an injury or as you are providing care, so check these periodically.

If spinal injury is suspected, then use the **jaw-thrust maneuver**. To perform a jaw-thrust maneuver, place your fingers behind the angles of the patient's lower jaw and then move the jaw upward. Keep the head in a neutral position as you move the jaw upward and open the mouth. If the patient's mouth remains closed, then use your thumbs to pull down the patient's lower lip to allow breathing.

FIGURE 15-13 A. Relaxation of the tongue back into the throat causes airway obstruction. **B.** The head tilt–chin lift maneuver combines two movements of opening the airway; head tilt is shown here.

© Jones & Bartlett Learning.

FIGURE 15-14 To perform the jaw-thrust maneuver, maintain the head in neutral alignment and place your fingers behind the angles of the lower jaw, and move the jaw upward. The completed maneuver should look like this.

FIGURE 15-14 reviews how to perform the jaw-thrust maneuver in an adult.

Recovery Position

If the patient is breathing adequately and has no signs of injury to the spine, hip, or pelvis, then place the person in the **recovery position**. This position

FIGURE 15-15 The recovery position is used to maintain an open airway in an adequately breathing patient with a decreased level of consciousness who has no spine, hip, or pelvic injuries. It allows vomitus, blood, and any other secretions to drain from the mouth.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

helps to maintain a clear airway in a patient with a decreased level of consciousness who has not sustained traumatic injuries and is breathing adequately unassisted (**FIGURE 15-15**). It also allows vomitus or secretions to drain from the mouth. Roll the patient onto their side so the head, shoulders, and torso move as a unit, without twisting. Then place the top hand under their cheek. Never place a patient who has a suspected head or spinal injury in the recovery position because in this position, the

YOU are the Provider

Part 2

You arrive at the scene and find two bystanders performing CPR on the patient, who appears to be in his late 40s. A second BLS ambulance is en route to the scene and will arrive in about 5 minutes. You perform a primary survey as your partner opens the AED.

Recording Time: 1 Minute

Appearance	Motionless; cyanosis of the face
Level of consciousness	Unresponsive
Airway	Open; clear of secretions or foreign bodies
Breathing	Absent
Circulation	No carotid pulse; skin is cool and dry; no gross bleeding

Your partner takes over performing compressions while one of the bystanders delivers mouth-to-mask ventilations. The other bystander tells you the patient had just dropped off a load of produce and sat down in his truck, and then he slumped over the steering wheel. By the time the bystander reached him, he was unresponsive and not breathing. The bystander further tells you he immediately called 9-1-1 and then began CPR.

3. What links in the chain of survival have been maintained at this point?
4. Why is it so crucial to minimize interruptions in CPR?

spine is not aligned, spinal stabilization is not possible, and further spinal injury could result. Likewise, if the patient has a hip or pelvic injury, then positioning the patient on their side could cause fractured bone ends to compress or sever large arteries and veins, resulting in severe internal bleeding. You should suspect an associated spinal injury in any unresponsive patient with a hip or pelvic injury until proven otherwise.

Breathing

A lack of oxygen (hypoxia), combined with too much carbon dioxide in the blood (hypercapnia), is lethal. Ventilations should be delivered over 1 second. This gentle, slow method of ventilating the patient prevents air from being forced into the stomach resulting in gastric distention.

Provide Artificial Ventilations

Ventilation is the exchange of air between the lungs and the environment. The act of assisting ventilation can be performed by one or two EMS providers. When you administer ventilations in the prehospital environment, use a bag-mask device when possible (**FIGURE 15-16**). Methods such as mouth-to-mouth or mouth-to-pocket mask pose heightened risk of disease transmission, especially in the context of active community transmission of airborne disease, such as the COVID-19 pandemic. Use devices that supply supplemental oxygen when

possible. Devices with an oxygen reservoir will provide higher percentages of oxygen to the patient. Regardless of whether you ventilate the patient with or without supplemental oxygen, you should observe the chest for visible rise to assess the effectiveness of your ventilations.

The specific steps of CPR are discussed later in this chapter. Adult BLS procedures are summarized in **TABLE 15-1**. Pediatric BLS procedures will be

TABLE 15-1 Review of Adult BLS Procedures	
Procedure	
Circulation	
Pulse check	Carotid artery
Compression area	Center of the chest, in between the nipples
Compression depth	2 to 2.4 in. (5 to 6 cm)
Compression rate	100 to 120/min
Compression-to-ventilation ratio (until advanced airway is inserted)	30:2
Foreign body obstruction	Responsive: abdominal thrusts (Heimlich maneuver); chest thrusts if patient is pregnant or has obesity Unresponsive: CPR
Airway	
Airway positioning	Head tilt–chin lift maneuver; jaw-thrust maneuver if spinal injury is suspected
Breathing	
Ventilations	1 breath every 6 seconds (10 breaths/min); about 1 second per breath; visible chest rise
Ventilations with advanced airway placed	1 breath every 6 seconds (a rate of 10 breaths/min)

Abbreviations: BLS, basic life support; CPR, cardiopulmonary resuscitation

FIGURE 15-16 When you provide ventilations, use a bag-mask device with one-way valve.

discussed later in this chapter. Resuscitation of a neonate is discussed in Chapter 35, *Obstetrics and Neonatal Care*.

Hyperventilation, ventilating too fast or with too much force, may cause increased intrathoracic pressure (pressure inside the chest cavity). Increased intrathoracic pressure reduces the amount of blood that returns to the heart, thus decreasing the effectiveness of chest compressions and resulting in the heart and brain receiving decreased amounts of oxygen. Rapid, forceful ventilations also increase the risk of gastric distention and may result in expulsion of gastric contents and aspiration of fluid or vomitus into the lungs.

Words of Wisdom

Atmospheric air is 21% oxygen. We exhale approximately 16% oxygen, which means we only use about 5% of inhaled oxygen. Therefore, mouth-to-mask or mouth-to-mouth ventilations are still effective until we can ventilate the patient with 100% oxygen. When providing ventilations via mouth-to-mask without an oxygen inlet, you can increase the percentage of expired oxygen by placing a nasal cannula on yourself.

Stoma Ventilation

Patients who have undergone a laryngectomy (surgical removal of the larynx) often have a permanent tracheal stoma at the midline in the neck. In this case, a stoma is an opening that connects the trachea directly to the skin (**FIGURE 15-17**). Because it is at the midline, the stoma is the only opening that will move air into the patient's lungs. Patients with a stoma should be ventilated with a bag-mask device or pocket mask device placed directly over the stoma.

Not all stomas are disconnected from the nose and mouth. If air leakage through the nose and mouth interferes with ventilation through the stoma, then cover the nose and mouth with your hand to make a seal. Use a pediatric or infant mask to ventilate through the stoma.

Gastric Distention

Artificial ventilation may result in the stomach becoming filled with air, a condition called **gastric distention**. Although it occurs more easily in

A

B

FIGURE 15-17 **A.** This stoma connects the trachea directly to the skin. **B.** Use a bag-mask device or pocket mask device to ventilate a patient with a stoma.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

children, this condition also happens frequently in adults. Gastric distention is likely to occur if you hyperventilate the patient. If you ventilate too forcefully, or if the patient's airway is not opened adequately, then the excess pressure opens the esophagus and allows air to enter the stomach. Therefore, it is important for you to give slow, gentle breaths. Such breaths are also more effective in ventilating the lungs. Excessive inflation of the stomach is dangerous because it can cause the patient to vomit during CPR. It can also reduce lung volume by exerting pressure on the diaphragm.

If massive gastric distention interferes with adequate ventilation, then contact medical control. Check the airway again and reposition the patient, watch for rise and fall of the chest, and avoid giving forceful breaths. Have a suction unit available in case the patient vomits. Remember, mortality increases significantly if aspiration occurs. Advanced airway adjuncts can also eliminate gastric distention

because the air goes directly into the lungs. If a paramedic is available, the paramedic can insert an orogastric or nasogastric tube to decompress the stomach or may intubate the patient to ensure ventilation without the possibility of gastric distention or aspiration. Chapter 11, *Airway Management*, lists adjuncts appropriate at the AEMT level.

One-Rescuer Adult CPR

When you provide CPR alone, you must provide a continuous cycle of 30 chest compressions followed by two artificial ventilations (a ratio of 30:2). To perform one-rescuer adult CPR, follow the steps in **SKILL DRILL 15-2**.

NR Skill

Skill Drill 15-2 Performing One-Rescuer Adult CPR

Step 1

Take standard precautions. Establish unresponsiveness and call for additional help.

Step 2

Position the patient properly (supine) on a flat surface. Check for breathing and a carotid pulse for no more than 10 seconds.

Step 3

If pulse and breathing are absent, then perform CPR until an AED is available. Kneel at the patient's side. Place your hands in the proper position for delivering external chest compressions, as described previously. Give 30 chest compressions at a rate of 100 to 120 per minute for an adult. Each set of 30 compressions should take about 17 seconds.

Step 4

Open the airway according to your suspicion of spinal injury.

Step 5

Give two ventilations of 1 second each and observe for visible chest rise. Continue cycles of 30 chest compressions and two ventilations until additional personnel arrive or the patient starts to move.

Two-Rescuer Adult CPR

You and your team should be able to perform one-rescuer and two-rescuer CPR with ease. Two-rescuer CPR is preferred because it is less tiring and it facilitates effective chest compressions. In fact, a team approach to CPR and AED use is far superior to the one-rescuer approach. Once one-rescuer CPR is in progress, additional rescuers can be easily added to the procedure. Before

assisting with CPR, a second rescuer should apply the AED and then set up airway adjuncts, including a bag-mask device and suction, and insert an oropharyngeal (oral) airway. When the first rescuer completes a cycle of 30 compressions, the first rescuer should move to the head and give two ventilations while the second rescuer moves into position to provide chest compressions. To perform two-rescuer adult CPR, follow the steps in **SKILL DRILL 15-3**.

Skill Drill 15-3 Performing Two-Rescuer Adult CPR

NR Skill

Step 1

Take standard precautions. Establish unresponsiveness while your partner moves to the patient's side to be ready to deliver chest compressions.

Step 2

If the patient is unresponsive, then simultaneously check for breathing and palpate for a carotid pulse; take no more than 10 seconds to do this.

Step 3

If the patient is not breathing and has no pulse, then begin CPR, starting with chest compressions. Give 30 chest compressions at a rate of 100 to 120 per minute. If an AED is available, then apply it and follow its voice prompts. Do not interrupt chest compressions to apply the AED pads.

Step 4

Open the airway according to your suspicion of spinal injury.

(continues)

Skill Drill 15-3 Performing Two-Rescuer Adult CPR (*continued*)

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 5

Give two ventilations of 1 second each and observe for visible chest rise. Perform five cycles of 30 compressions and two ventilations (this should take about 2 minutes). After 2 minutes of CPR, the compressor and ventilator should switch positions. It should not take longer than 5 seconds to switch positions. Reanalyze the patient's cardiac rhythm with the AED every 2 minutes and deliver a shock if indicated. Continue cycles of 30 chest compressions and two ventilations until additional providers arrive allowing you to initiate ALS care, or until the patient starts to move.

Words of Wisdom

When CPR is in progress on a patient who has an advanced airway device in place (eg, ET tube, King LT supraglottic airway, i-gel supraglottic airway), cycles of CPR are not indicated. Compressions should be continuous at a rate of 100 to 120 per minute and ventilations should occur at a rate of one breath every 6 seconds (10 breaths/min). Although there is no synchronization of compressions and ventilations, it is more effective to deliver ventilations during the recoil of the chest than during the actual compression.

Switching Positions

It is critical to switch rescuers during CPR to maintain high-quality compressions. After five cycles of CPR (about 2 minutes), the rescuer providing compressions to the patient (the compressor) will begin to tire, and compression quality will decrease. Therefore, compressors should switch positions every 2 minutes. If there are only two rescuers on scene, the two rescuers will alternate positions. If additional rescuers are available, the compressor should rotate every 2 minutes. During switches, every effort should be made to minimize

the time that no compressions are being administered. It should take less than 5 seconds to switch compressors.

The switch between the two rescuers can be easily accomplished. Rescuer one (the first compressor) should finish the cycle of 30 compressions while the second rescuer moves to the opposite side of the chest and moves into position to begin compressions. Rescuer one should deliver two rescue breaths and then rescuer two should take over compressions by administering 30 chest compressions. Rescuer one will then deliver two ventilations and the CPR cycles will continue as needed until the next 2-minute mark (five cycles) is reached, at which time the process will be repeated.

Crew Resource Management

In the past, EMS training focused on mastering individual skills and did not always include the benefits of an effective team-based approach. Specifically, there was a lack of focus on the behavioral and communication skills that were necessary when in a team environment. Also known as the “pit crew” approach, this approach can be particularly effective in cardiac arrest resuscitation. Each member is assigned a particular role prior to treating an actual

FIGURE 15-18 Collaboration and communication are crucial aspects of crew resource management.

© Glen E. Elman.

patient in cardiopulmonary arrest. This helps to prevent the potential confusion and lack of direction that may occur on a chaotic scene.

Crew resource management (CRM) is a way for team members to work together with the team leader to develop and maintain a shared understanding of the emergency situation. CRM allows team members with different skill sets to collaborate and communicate, fulfill their roles and responsibilities, and achieve the shared goal of the best possible patient outcome (**FIGURE 15-18**). Under the CRM model, each team member is responsible for maintaining situational awareness of the patient's current condition and sharing any crucial information with the team leader. Likewise, the team leader is responsible for listening to any crucial information you or other team members provide and incorporating that information into the decision-making process.

Even in the often loud and hectic environment in which EMS providers work, when you believe there is an immediate or potential problem you must bring it to the team leader's attention. CRM recommends using the PACE mnemonic:

- P Probe.** Look or ask to confirm the problem.
- A Alert.** Communicate the problem to the team leader.
- C Challenge.** If the issue is not corrected, challenge the team's present course of action that is leading to the problem. For example, "Lieutenant, I think this additional action should be taken. Do you agree?"
- E Emergency.** If the problem is clear and critical (such as an immediate safety issue), then

immediately communicate the emergency to the entire team.

The CRM model does not mean you are free to ignore the chain of command within the incident command system. Rather, it means you are empowered to provide the team leader and other team members with immediate feedback in the event of a potential threat to the patient's or crew's safety. It also means the team, as a whole, recognizes the importance of getting input from each individual and that the team is committed to fostering open communication. CRM empowers people to speak up clearly and concisely when they detect a problem or potential problem.

Documentation and Communication

It is essential to speak up when there is an error of *omission* (something not being done) or *commission* (something being done incorrectly or inappropriately). It is also important to avoid unrelated side conversations and commentary when managing a patient. Nonessential conversation can be distracting, creates unnecessary noise, and can lead to errors in patient care.

Whether you are a code team member or a code team leader, know your role and the roles of the other team members during the resuscitation attempt. This helps you anticipate and understand what steps are coming next and how essential your role is as part of the resuscitation attempt. Regardless of the skills you are trained and appropriately authorized to perform, it is essential to the success of resuscitation that you are prepared, have practiced regularly, have mastered the algorithms, and are committed to success.

Code Team Member Roles

A code team member may be called on to perform any of the following roles (and more):

- **Ventilator**—manages the airway. This team member's duties include suctioning the patient, ventilating the patient with a bag-mask device, inserting an advanced airway device (eg, LMA, Combitube, or King LT), and maintaining manual in-line stabilization of the head and neck.

- **Active compressor**—provides high-quality chest compressions. The responsibility of this team member is to compress for 2 minutes and be the on-deck compressor for 2 minutes.
- **On-deck compressor**—at the 2-minute point, this team member needs to be ready to relieve the compressor without any interruption in compressions. Other functions include assisting with application of a mechanical CPR adjunct device (if available), assessing vital signs, and preparing the patient for transport.
- **Other support personnel**—responsible for operating the AED, gaining venous (IV or IO) access, providing documentation for the patient care report, and supporting family members.

Code Team Leader Roles

Every resuscitation team needs a leader to organize the efforts of the group. Clearly, the code team leader must know all of the specific skills and be able to expertly perform each skill—occasionally the code team leader will serve as the backup for a

team member who may be having difficulty inserting a tube or gaining IV/IO access. The code team leader is often responsible for ensuring everything gets done at the right time in the right way.

The roles of the code team leader may include any or all of the following:

- Obtaining the patient's history and performing the physical exam
- Keeping track of the time
- Making a medication decision following the algorithm
- Clearly delegating tasks to code team members
- Completing documentation after the resuscitation attempt
- Talking with medical control
- Controlling the resuscitation scene

Code team leaders must also model excellent behavior and leadership skills for their team and all others who may be involved in the resuscitation. The code team leader helps train future team leaders, seeks to improve the effectiveness of the entire team through continuous quality improvement, and evaluates processes after the resuscitation to help prepare for the next code.

Words of Wisdom

Many EMS systems have implemented a pit crew approach to the management of cardiac arrest. The term originated in motor racing, in which teams of technicians rapidly assess and repair vehicles in a matter of seconds. Following this model, each resuscitation team member is assigned a specific role before beginning care of the cardiac arrest patient. For example:

- AEMT 1 will be the team leader.
- AEMT 2 and AEMT 3 will perform CPR.
- AEMT 4 will operate the AED.

This model clarifies each team member's role and responsibilities and minimizes confusion on the scene. If there are only two AEMTs on scene initially—as is the situation in many cases—then a plan should be developed to integrate additional rescuers into the resuscitation effort as they arrive. This preplanned approach allows rescuers to accomplish multiple steps and assessments simultaneously, rather than the slower, sequential manner used by individual rescuers. Therefore, the pit crew model minimizes the time to first compression. The success of this team approach depends on preplanning, practice, and thorough familiarity with the cardiac arrest algorithm.

ROSC and Postresuscitation Support

Postresuscitation care is an important component of caring for cardiac arrest patients and is the fifth link in the AHA chain of survival. If an effective cardiac rhythm is restored in the field, you should provide immediate transport because the patient needs careful monitoring and titrated therapy that can most effectively be provided in an intensive care unit. During transport, it is imperative that you monitor the patient's blood glucose level and ensure effective ventilation with the proper rate and tidal volume. Always leave AED pads in place. In the event the patient goes into cardiopulmonary arrest again, you will save valuable time if you can immediately analyze the rhythm without replacing the AED pads.

The following is a summary of post-cardiac arrest care:⁵

1. Optimize ventilation and oxygenation
 - a. Maintain oxygen saturation $\geq 94\%$
 - b. Consider advanced airway and waveform capnography
 - c. Do not hyperventilate

2. Treat hypotension (systolic blood pressure <90 mm Hg)
 - a. IV/IO bolus
 - b. Consider treatable causes (Hs & Ts)
 - c. Paramedic backup for administration of a vasopressor infusion
3. Advanced critical care in the ED, including:
 - a. 12-lead electrocardiogram to rule out STEMI (ST-elevation myocardial infarction) or AMI (acute myocardial infarction)
 - b. Coronary reperfusion via percutaneous coronary intervention (PCI)
 - c. Targeted temperature management for comatose patients

conditions, manual chest compressions cannot equate to normal cardiac output. In addition, factors such as rescuer fatigue or inaccurate depth or rate of compressions can further impede the resuscitation process.

Several mechanical devices are available to assist emergency responders in maximizing blood flow during CPR. Although improved patient outcomes have not yet been documented, these devices may be considered for use as an adjunct to CPR in select settings when used by properly trained personnel for patients in cardiac arrest in the prehospital or in-hospital setting. These specific settings include instances when limited rescuers

Words of Wisdom

The goals of post–cardiac arrest care include the following:

1. Targeted temperature management (TTM)
 - Therapeutic hypothermia has been shown to improve neurologic outcomes when induced soon after ROSC. This intervention is not possible in the field; your responsibility is to provide rapid transport to the closest appropriate facility for treatment.
2. Ventilation optimization
 - Avoid excessive ventilation, which will decrease oxygen saturation levels, resulting in reduced cerebral perfusion. Ventilate adults at 10 breaths/min and monitor end-tidal carbon dioxide levels. Levels should be maintained at 35 to 40 mm Hg.
 - Excessive ventilation can also increase intrathoracic pressure, leading to adverse hemodynamic effects by decreasing venous return to the heart.
3. Hemodynamic optimization
 - Administer IV fluid boluses of an isotonic crystalloid to maintain a systolic blood pressure of at least 90 mm Hg. Also consider calling for paramedic backup to administer vasopressors, especially if transport time is long.

Remember to monitor glucose levels! Administer IV D₅₀W as needed to maintain glucose levels within a normal range.

Special Populations

On occasion, you may encounter a patient who has a left ventricular assist device (LVAD). The LVAD is a mechanical pump that is implanted in the chest and helps pump blood from the left ventricle to the aorta. A tube from the device passes through the skin and is attached to an external power source that patients wear on their belts or on over-the-shoulder harnesses. The LVAD is commonly implanted in patients with severe heart failure or in those who are awaiting a heart transplant. If the LVAD is working, then you will hear a humming sound when listening to the chest with a stethoscope. Blood flows continuously through the LVAD, and the more assistance the LVAD is providing to the heart, the weaker the patient's pulse will be. In some LVAD patients, you may not feel a pulse at all, even though they are responsive and alert. When transporting a patient who has an LVAD, be sure to bring all LVAD equipment with you and ensure the receiving facility is capable of caring for the patient's specific needs.

Know the location of LVAD patients in your service area. If possible, visit with the patient prior to any emergency to determine the specific device and to obtain instructions. Family members are usually knowledgeable about the device; use them as a source of information.

LVAD coordinators are usually available for consult 24 hours per day. These medical professionals typically work at the same facility that placed the device, so they should also be familiar with the patient. Follow your local protocols or contact medical control regarding the treatment of a patient with an LVAD. For more information on the LVAD, see Chapter 38, *Patients With Special Challenges*.

Devices and Techniques to Assist Circulation

The effectiveness of CPR depends on the amount of blood circulated throughout the body as a result of chest compressions. However, even under ideal

FIGURE 15-19 An active compression-decompression cardiopulmonary resuscitation device.

Provided with permission by ZOLL Medical.

are available, when CPR is prolonged, or when CPR is required in a moving ambulance.

Active Compression-Decompression CPR

Active compression-decompression CPR is a technique that involves compressing the chest and then actively pulling it back up to its neutral position or beyond (decompression). This technique may increase the amount of blood that returns to the heart and, thus, the amount of blood ejected from the heart during the compression phase. **FIGURE 15-19** shows an active compression-decompression CPR device. It features a suction cup that is placed in the center of the chest. After compressing the chest to the proper depth, the rescuer pulls up on the handle of the device to provide active decompression of the chest, thus ensuring the chest returns to at least its neutral position or even beyond neutral.

Impedance Threshold Device

An **impedance threshold device (ITD)** is a valve device placed between the ET tube and a bag-mask device; it may also be placed between the bag and mask if an ET tube is not in place. The ITD is designed to limit the air entering the lungs during the recoil

FIGURE 15-20 An impedance threshold device.

Courtesy of Advanced Circulatory Systems, Inc.

phase between chest compressions (**FIGURE 15-20**). This results in negative intrathoracic pressure that may draw more blood toward the heart, ultimately resulting in improved cardiac filling and circulation during each chest compression. An ITD selectively prevents unnecessary air from rushing into the chest, maximizing the vacuum during the recoil phase of the compression. This results in enhanced return of blood that increases cardiac output, blood pressure, and perfusion to vital organs, and ultimately improves survival rates. Use an ITD to help improve circulation during CPR and increase the ROSC in cardiac arrest patients. The ITD may be

Words of Wisdom

Another alternative to conventional CPR is *interposed abdominal compression*. The same standard sequence of CPR steps is followed, with the addition of midabdominal compressions in counterpoint to chest compressions. A third rescuer places their overlapping hands just above the umbilicus and uses the same technique to compress the abdomen when the chest is not being compressed. Always follow local protocols and current AHA guidelines.⁶

considered when used together with devices that provide active compression-decompression CPR. It is *not* currently recommended for use with conventional CPR. If the patient's pulse returns, then the ITD should be removed from the ventilation system because it is designed to be used in conjunction with compressions. Ensure you understand research trends regarding the effectiveness of the ITD.

Mechanical Piston Device

A **mechanical piston device** is a device that depresses the sternum via a compressed gas-powered or electric-powered plunger mounted on a backboard (**FIGURE 15-21**). The patient is positioned supine on

the backboard, with the piston positioned on top of the patient with the plunger centered over the patient's thorax in the same manner as with manual chest compressions. The device is then secured to the backboard.

The mechanical piston device allows rescuers to configure the depth and rate of compressions, resulting in consistent delivery. This frees the rescuer to complete other tasks and eliminates rescuer fatigue that results from continuous delivery of manual chest compressions. These devices have been available for many years. The latest versions of these devices offer you the option of providing compressions using a battery instead of an oxygen tank or a compressed air system, thus eliminating the tanks and hoses.

Load-Distributing Band CPR or Vest CPR

The **load-distributing band (LDB)** is a circumferential chest compression device composed of a constricting band and backboard (**FIGURE 15-22**). The device is either electrically or pneumatically driven to compress the heart by putting inward pressure on the thorax.

**A****B**

FIGURE 15-21 **A.** A mechanical piston device. **B.** The device in use.

A: Courtesy of LUCAS CPR (Physio Control Inc.); **B:** © Jones & Bartlett Learning.

FIGURE 15-22 A load-distributing band.

Provided with permission by ZOLL Medical.

As with the mechanical piston device, use of the LDB frees up the rescuer to complete other tasks. The device weighs less than the early-version mechanical piston devices and can be easier to apply.

Although a mechanical CPR device may be a reasonable alternative to conventional CPR in specific settings, manual chest compressions remain the standard of care. If your EMS system uses a mechanical CPR device, then it is crucial to practice using it frequently to ensure you can rapidly apply it. Remember to minimize interruptions to chest compressions while the device is being applied.

Infant and Child CPR

In most cases, cardiac arrest in infants and children follows respiratory arrest, which triggers hypoxia and **ischemia** (decreased oxygen supply) of the heart. Children consume oxygen two to three times as rapidly as adults, so you must first focus on opening the airway and providing artificial ventilation.

Often, this will be enough to allow the child to resume spontaneous breathing and, thus, prevent cardiac arrest. Therefore, airway and breathing are the focus of pediatric BLS (**TABLE 15-2**).

Respiratory issues leading to cardiopulmonary arrest in children can have many different causes, including the following:

- Injury, both blunt and penetrating
- Infections of the respiratory tract or another organ system (croup, epiglottitis)
- A foreign body in the airway
- Submersion (drowning)
- Electrocution
- Poisoning or drug overdose
- Sudden infant death syndrome (SIDS)

Determining Responsiveness

Never shake a child to determine whether the patient is responsive, especially if the possibility of a neck or back injury exists. Instead, gently tap the child on the shoulder, and say loudly, “Are you

YOU

are the Provider

Part 3

With CPR ongoing, you open the AED pads and prepare to apply them to the patient’s chest. You note the patient has a medication patch on the right upper part of his chest. You also see a bulge with a scar on the left upper part of his chest. You apply the AED pads, analyze the patient’s cardiac rhythm, and receive a “shock advised” message. After delivering the shock, you and your partner resume CPR. The second ambulance arrives, and one EMT moves into position to take over compressions at the end of the cycle and a second EMT prepares to take over ventilations.

Recording Time: 4 Minutes	
Level of consciousness	Unresponsive
Respirations	Absent (baseline); 2 breaths are being given after every 30 chest compressions; chest rise is visible with each breath
Pulse	Absent (baseline); femoral pulse is palpable with chest compressions
Skin	Pale
Blood pressure	Not measurable
Oxygen saturation (Spo ₂)	Not measurable

5. Should you remove the medication patch or leave it in place? Why or why not?
6. What does the bulge and scar over the patient’s left chest indicate? How will this affect the way you treat the patient?
7. Which rhythms will the AED defibrillate?

TABLE 15-2 Review of Pediatric BLS Procedures

Procedure	Infants (between age 1 month and 1 year ^a)	Children (1 year to onset of puberty ^b)
Circulation		
Pulse check	Brachial artery	Carotid or femoral artery
Compression area	Just below the nipple line	In the center of the chest, in between the nipples
Compression width	Two-finger technique or two-thumb-encircling-hands technique	Heel of one or both hands
Compression depth	At least one-third anterior-posterior diameter (about 1.5 in. [4 cm])	At least one-third anterior-posterior diameter (about 2 in. [5 cm])
Compression rate	100 to 120/min	100 to 120/min
Compression-to-ventilation ratio (until advanced airway is inserted)	30:2 (one rescuer); 15:2 (two rescuers) ^c	30:2 (one rescuer); 15:2 (two rescuers) ^c
Foreign body obstruction	Responsive: Back blows and chest thrusts Unresponsive: CPR	Responsive: Abdominal thrusts (Heimlich maneuver) Unresponsive: CPR
Airway		
	Head tilt–chin lift maneuver; jaw-thrust maneuver if spinal injury is suspected	Head tilt–chin lift maneuver; jaw-thrust maneuver if spinal injury is suspected
Breathing		
Ventilations	1 breath every 2 to 3 seconds (20 to 30 breaths/min); about 1 second per breath; visible chest rise	1 breath every 2 to 3 seconds (20 to 30 breaths/min); about 1 second per breath; visible chest rise
Ventilations with advanced airway placed	1 breath every 6 seconds (a rate of 10 breaths/min)	1 breath every 6 seconds (a rate of 10 breaths/min)

Abbreviations: BLS, basic life support; CPR, cardiopulmonary resuscitation

^aThe American Heart Association defines neonatal patients as birth to age 1 month, and infants as age 1 month to 1 year. Neonatal resuscitation is covered in Chapter 35, *Obstetrics and Neonatal Care*.

^bOnset of puberty is approximately 12 to 14 years of age, as defined by secondary characteristics (eg, breast development in girls and armpit hair in boys).

^cPause compressions to deliver ventilations.

okay?” (FIGURE 15-23). With an infant, gently tap the soles of the feet. If a child is responsive but struggling to breathe, allow the child to remain in whatever position is most comfortable.

If you find an unresponsive, apneic, and pulseless child while you are alone and off duty, and you did not witness the child’s collapse, perform CPR beginning with chest compressions for approximately five cycles (about 2 minutes), and then stop

to call 9-1-1 and retrieve an AED. Do not call 9-1-1 right away, as you would with an adult. Remember, cardiopulmonary arrest in children is most often the result of respiratory failure, not a primary cardiac event. Therefore, children will require immediate restoration of oxygenation, ventilation, and circulation, which can be accomplished by immediately performing five cycles (about 2 minutes) of CPR before activating the EMS system.

FIGURE 15-23 Never shake a child to determine responsiveness. Instead, gently tap on the shoulder (child) or tap the soles of the feet (infant), and speak loudly.

© Jones & Bartlett Learning.

Special Populations

Although uncommon, you may encounter a child whose cardiac arrest was caused by a primary cardiac event rather than a respiratory problem. If an otherwise healthy child without an apparent respiratory condition suddenly collapses and you witness it, first confirm that the child is in cardiac arrest. If you are alone without a mobile phone, leave the child to call 9-1-1 and get an AED before beginning CPR. If you are not alone, send someone to call 9-1-1 and get an AED while you begin CPR. The sudden collapse of an otherwise healthy child does not indicate a respiratory problem; instead, it suggests a primary cardiac event that may respond to defibrillation. Therefore, it is critical to get the AED to the child's side as soon as possible.

Check for Breathing and a Pulse

After you establish responsiveness, assess breathing and circulation. As with an adult, this assessment can occur simultaneously and should take no longer than 10 seconds. Visualize the chest for signs of breathing and palpate for a pulse in a large central artery. You can usually palpate the carotid or femoral pulse in children older than 1 year, but it is difficult in infants. Therefore, in infants, palpate the brachial artery, which is located on the inner side of the arm, midway between the elbow and shoulder. Place the tips of your index and middle fingers on the inside of the biceps, and press lightly toward the bone. CPR is required if the infant or child is not breathing or is

not breathing normally (agonal gasps), and a pulse is absent (or less than 60 beats/min).

As with an adult, an infant or child must be lying on a hard, flat surface for effective chest compressions. If you need to carry an infant while providing CPR, your forearm and hand can serve as the flat surface. Use your palm to support the infant's head. In this way, the infant's shoulders are elevated, and the head is slightly tilted back in a position that will keep the airway open. Ensure the infant's head is not higher than the rest of the body.

The technique for chest compressions in infants and children differs from adults because of several anatomic differences, including the position of the heart, the size of the chest, and the fragile organs of a child. The liver (immediately under the right side of the diaphragm) is relatively large and fragile, especially in infants. The spleen, on the left, is smaller and more fragile in children than in adults. These organs are easily injured if you are not careful in performing chest compressions, so be sure your hand position is correct before you begin. The chest of an infant is smaller and more pliable than that of an older child or adult; therefore, use only two fingers to compress the chest, or use the two-thumb-encircling-hands technique as performed with two providers. If two rescuers are performing CPR on an infant, use the two-thumb-encircling-hands technique to deliver chest compressions (**FIGURE 15-24**). In children, especially those older than 8 years, you can use the heel of one or both hands to compress the chest.

Follow the steps in **SKILL DRILL 15-4** to perform infant chest compressions.

FIGURE 15-24 Chest compressions should be given with the hands encircling the infant and thumbs side by side.

© Jones & Bartlett Learning.

Skill Drill 15-4 Performing Infant Chest Compressions

Step 1

Take standard precautions. Place the infant on a firm, flat surface, and keep the head in an open airway position. You can also use a pad or wedge under the shoulders and upper body to keep the head from tilting forward.

Step 2

A single provider may use the two-fingers technique or the two-thumb-encircling-hands technique (preferred), as performed with two providers. If using the two-finger technique, imagine a horizontal line drawn between the nipples. Place two fingers in the middle of the sternum, just below the nipple line. Use two fingers to compress the sternum at least one-third the anterior-posterior diameter of the chest (approximately 1.5 inches [4 cm] in most infants). Compress the chest at a rate of 100 to 120 per minute. After each compression, allow the sternum to return briefly to its normal position. Allow equal time for compression and relaxation of the chest. Do not remove your fingers from the sternum, and avoid jerky movements.

© Jones & Bartlett Learning.

Coordinate compressions and ventilations in a 30:2 ratio if you are working alone, and 15:2 if you are working with a trained bystander or another health care provider. Ensure the infant's chest fully recoils in between compressions and that the chest visibly rises with each ventilation. You will find this easier to do if you use your free hand to keep the head in the open airway position. If the chest does not rise, or rises only a little, then use a head tilt-chin lift to open the airway. Reassess the infant for signs of spontaneous breathing or a pulse after five cycles (about 2 minutes) of CPR.

SKILL DRILL 15-5 shows the steps for performing CPR in children between 1 year of age and the onset of puberty.

Switching rescuer positions is the same for children as it is for adults: every five cycles (2 minutes)

of CPR. Remember, if the child is past the onset of puberty, use the adult CPR sequence, including the use of the AED.

Airway

Infants and toddlers often put toys and other objects in their mouths; therefore, foreign body obstruction of the upper airway is common. Make sure the upper airway is patent when managing pediatric respiratory emergencies or cardiopulmonary arrest. If the child is unresponsive and lying in a supine position, the airway may become obstructed when the tongue and throat muscles relax and the tongue falls backward.

If the child is unresponsive but breathing adequately, place the child in the recovery position

Skill Drill 15-5 Performing CPR on a Child**Step 1**

Take standard precautions. Place the child on a firm, flat surface. Place the heel of one or two hands (if treating a larger child) in the center of the chest, in between the nipples. Avoid compression over the lower tip of the sternum, which is called the xiphoid process.

**Step 2**

Compress the chest at least one-third the anterior-posterior diameter of the chest (approximately 2 inches [5 cm] in most children) at a rate of 100 to 120 times/min. Coordinate compressions with ventilations in a 30:2 ratio for one rescuer or 15:2 ratio for two rescuers, making sure the chest rises with each ventilation. At the end of each cycle, pause for two ventilations. Reassess for a pulse after 2 minutes. If there is no pulse and an AED is available, resume CPR and apply the AED pads.

Step 3

If the child regains a pulse of greater than 60 beats/min and resumes effective breathing, then place the child in a position that allows for frequent reassessment of the airway and vital signs during transport.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

to maintain an open airway and allow drainage of saliva, vomitus, or other secretions from the mouth (**FIGURE 15-25**). Do not use this position if you suspect injury to the spine, hips, or pelvis unless you can secure the child to a backboard that can be tilted to the side. If the child is responsive, but breathing is labored, provide prompt transport to the closest appropriate hospital.

Opening the airway in an infant or child is done by using the same techniques as used for an adult. However, because a child's neck is so flexible, the techniques should be slightly modified. The jaw-thrust maneuver is the best method to use if you suspect a spinal injury in a child. If a second rescuer is present, that rescuer should immobilize the child's cervical spine. If you do not suspect spinal

FIGURE 15-25 A child who is unresponsive but breathing adequately should be placed in the recovery position to allow saliva or vomitus to drain from the mouth.

© Jones & Bartlett Learning.

FIGURE 15-26 Use the head tilt–chin lift maneuver to open the airway in a child who has not sustained a traumatic injury. Do not overextend the neck.

© Jones & Bartlett Learning.

injury, then use the head tilt–chin lift maneuver but modified so that, as you tilt the head back, you are moving it only into the neutral position or a slightly extended position (**FIGURE 15-26**).

Head Tilt–Chin Lift Maneuver

Perform the head tilt–chin lift maneuver in a child in the following manner:

1. Place one hand on the child's forehead, and gently tilt the head back, with the neck slightly extended.
2. Place two or three fingers (not the thumb) of your other hand under the child's chin, and lift the jaw upward and outward. Do not close the mouth or push under the chin; either move may obstruct rather than open the airway.
3. Remove any visible foreign body or vomitus.

Jaw-Thrust Maneuver

Perform the jaw-thrust maneuver in a child in the following manner:

1. Place two or three fingers under each side of the angle of the lower jaw; lift the jaw upward and outward.
2. If the jaw thrust alone does not open the airway and cervical spine injury is not a consideration, tilt the head slightly. If cervical spine injury is suspected, use a second rescuer to immobilize the cervical spine.

Remember, the head of an infant or young child is disproportionately large in comparison with the chest and shoulders. As a result, when a child is lying supine, especially on a backboard, the head will bend forward (hyperflexion) onto the upper chest. This position can partially or completely obstruct the upper airway. To avoid this possibility, place a wedge of padding under the child's upper chest and shoulders (torso).

Provide Rescue Breathing

If the child is not breathing but has a pulse, open the airway and deliver one breath every 2 to 3 seconds (20 to 30 breaths/min) (**FIGURE 15-27**). If the child is not breathing and does not have a pulse, deliver 2 rescue breaths after every 30 chest compressions (15 chest compressions if two rescuers are present). Each ventilation should last about 1 second and should produce visible chest rise. Use the proper-size mask and ensure an adequate mask-to-face seal.

FIGURE 15-27 Open the child's airway and provide rescue breathing.

© Bruce Ayres/The Image Bank/ Getty Images Plus/Getty Images.

If an infant or small child is breathing, provide prompt transport. Again, a child who is in respiratory distress should be allowed to stay in whatever position is most comfortable. Children who are unresponsive but breathing with difficulty should be kept in a position that allows you to manage the airway and provide ventilatory support, if needed.

In a child with a tracheostomy tube in the neck, remove the mask from the bag-mask device and connect it directly to the tracheostomy tube to ventilate the child. If a bag-mask device is unavailable, a face mask with one-way valve or other barrier device over the tracheostomy site can be used. Place your hand firmly over the child's mouth and nose to prevent the artificial breaths from leaking out of the upper airway.

Words of Wisdom

An injured child with a serious airway or breathing problem is likely to need full-time attention from two providers. Therefore, it is important for you to arrange for backup from another unit as soon as possible—perhaps even before you arrive at the scene. Paramedic backup is preferable to provide support as needed.

Special Populations

Neonatal resuscitation is quite different from that of infant CPR. Follow the steps listed for any newborn requiring resuscitation:

1. Perform the initial steps in stabilization (provide warmth, clear airway if necessary, dry, stimulate).
2. Provide positive-pressure ventilation with SpO₂ (oxygen saturation) monitoring.
3. Administer chest compressions if the heart rate is below 60 beats/min.
4. Consider laryngeal mask airway, or paramedic backup for intubation, continue chest compressions, and coordinate with positive-pressure ventilation.
5. If the heart rate remains below 60 beats/min, gain IV/IO access, and call paramedic backup for administration of IV epinephrine, and consider hypovolemia or pneumothorax.

Following the initial steps of resuscitation, the need for and extent of further resuscitation is based on the assessment of three key parameters: respiratory effort, heart rate, and color. See Chapter 35, *Obstetrics and Neonatal Care*, for more information on neonatal resuscitation.

Interrupting CPR

CPR is a crucial, life-saving procedure that provides minimal circulation and ventilation until the patient can receive defibrillation, ALS treatment, and definitive care at the ED. No matter how well CPR is performed, however, it is rarely enough to save a patient's life. If paramedic backup is unavailable at the scene, you must provide transport based on your local protocols and continue CPR en route. Keep in mind, movement from a vehicle can interfere with analysis by an AED. Contact the manufacturer to confirm if the model you have can be used in a moving vehicle. Otherwise, the ambulance must be stopped each time you utilize the AED. En route to the ED, consider requesting a paramedic rendezvous if available. This will provide additional ALS care to the patient sooner, thereby improving the patient's chance for survival. However, not all EMS systems have paramedic backup support available to them, especially in rural settings. For those areas where it is available, consider calling early for air transport. Their goal is to provide service to rural

Special Populations

Children in respiratory distress often struggle to breathe. As a result, they usually position themselves in a way that keeps the airway open enough for air to move. Let the child stay in that position as long as their breathing remains adequate. If you and your partner arrive at the scene and find that the infant or child is not breathing or has cyanosis, immediate management (including rescue breathing and supplemental oxygen) is essential. Consider requesting paramedic assistance, if available.

Remember that a child's airway is smaller than an adult's. Therefore, there is greater resistance to air flow. As a result, you will need to use *slightly* more ventilatory pressure to inflate the lungs. You will know you are giving the correct tidal volume when you see the chest rise. Infants and children should be ventilated once every 2 to 3 seconds (at a rate of 20 to 30 breaths/min). Do not ventilate too fast or use too much force.

If air enters freely with your initial breaths and the chest rises, then the airway is clear. If air does not enter freely, then check the airway for obstruction. Reposition the patient to open the airway, and attempt to give another breath. If air still does not enter freely, you must take steps to relieve the obstruction.

areas where advanced care may not be readily available or transport times are long.

Try not to interrupt CPR for more than a few seconds, except when absolutely necessary. For example, if you have to move a patient up or down stairs, then continue CPR until you arrive at the head or foot of the stairs, interrupt CPR at a mutually agreed-on signal, and move quickly to the next level where you can resume CPR. Do not move the patient until all transport arrangements are made so that interruptions to CPR can be kept to a minimum. See Chapter 6, *Lifting and Moving Patients*, to review patient lifting and moving techniques.

Chest compression fraction is the total percentage of time during a resuscitation attempt in which chest compressions are being performed. Make every effort to maintain a chest compression fraction of at least 60% (the higher the better). The more frequent the interruptions in chest compressions are, the lower the compression fraction will be. Low compression fractions result in worse patient outcomes. Most modern cardiac monitors will provide information about chest compression fraction that you can review after a cardiac arrest. If possible, routinely review this information after every arrest so you can learn ways to improve the chest compression fraction and improve on other key performance indicators.

When Not to Start CPR

As an AEMT, it is your responsibility to start CPR on virtually all patients who are in cardiac arrest. There are only three general exceptions to the rule.

First, do not start CPR if the scene is unsafe. Ensure scene safety in cardiac arrest situations, just as you would on any other call.

Second, do not start CPR if the patient has obvious signs of death. Obvious signs of death include an absence of a pulse and breathing, along with any one of the following findings:

- **Rigor mortis**, or stiffening of the body after death
- **Dependent lividity** (livor mortis), a discoloration of the skin caused by pooling of blood (**FIGURE 15-28**)
- Putrefaction (decomposition of the body tissues)
- Mortal injury, such as decapitation, dismemberment, or burned beyond recognition

FIGURE 15-28 Dependent lividity is an obvious sign of death, caused by blood settling to the areas of the body not in firm contact with the ground. The lividity in this figure is seen as purple discoloration of the back, except in areas that are in firm contact with the ground (scapula and buttock).

© American Academy of Orthopaedic Surgeons.

Rigor mortis and dependent lividity develop after a patient has been dead for a long period.

Third, do not start CPR if the patient and their physician have previously agreed on a do-not-resuscitate (DNR) order or no-CPR order (**FIGURE 15-29**). DNR orders give you permission not to attempt resuscitation. This may apply only in situations in which the patient is known to be in the terminal stage of an incurable disease. In this situation, CPR would only prolong the patient's death. However, end-of-life issues can be complicated. Advance directives, such as living wills, may express the patient's wishes; however, these documents may not be readily producible by the patient's family or caregiver. In such cases, the safest course is to begin CPR under the rule of implied consent and then contact medical control for further guidance. However, if a valid DNR document or living will is produced, resuscitation efforts may be withheld. Learn your local protocols and the standards in your EMS system for treating terminally ill patients. Some EMS systems have electronic notes on patients who are preregistered with the system. These notes usually specify the amount and extent of treatment that is desired. Other states have specific DNR forms that allow EMS providers to withhold care when the patient, family, and physician have agreed in advance that such a course is most appropriate. It is essential that you understand your

OUT-OF-HOSPITAL DO-NOT-RESUSCITATE (OOH-DNR) ORDER
TEXAS DEPARTMENT OF STATE HEALTH SERVICES

This document becomes effective immediately on the date of execution for health care professionals acting in out-of-hospital settings. It remains in effect until the person is pronounced dead by authorized medical or legal authority or the document is revoked. Comfort care will be given as needed.

Person's full legal name _____ Date of birth _____ ☐ Male
☐ Female

A. Declaration of the adult person: I am competent and at least 18 years of age. I direct that none of the following resuscitation measures be initiated or continued for me: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Person's signature _____ Date _____ Printed name _____

B. Declaration by legal guardian, agent or proxy on behalf of the adult person who is incompetent or otherwise incapable of communication:

I am the: ☐ legal guardian; ☐ agent in a Medical Power of Attorney; OR ☐ proxy in a directive to physicians of the above-noted person who is incompetent or otherwise mentally or physically incapable of communication.

Based upon the known desires of the person, or a determination of the best interest of the person, I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Signature _____ Date _____ Printed name _____

C. Declaration by a qualified relative of the adult person who is incompetent or otherwise incapable of communication: I am the above-noted person's:

☐ spouse, ☐ adult child, ☐ parent, OR ☐ nearest living relative, and I am qualified to make this treatment decision under Health and Safety Code §166.088.

To my knowledge the adult person is incompetent or otherwise mentally or physically incapable of communication and is without a legal guardian, agent or proxy. Based upon the known desires of the person or a determination of the best interests of the person, I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Signature _____ Date _____ Printed name _____

D. Declaration by physician based on directive to physicians by a person now incompetent or nonwritten communication to the physician by a competent person: I am the above-noted person's attending physician and have:

☐ seen evidence of his/her previously issued directive to physicians by the adult, now incompetent; OR ☐ observed his/her issuance before two witnesses of an OOH-DNR in a nonwritten manner.

I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Attending physician's signature _____ Date _____ Printed name _____ Lic# _____

E. Declaration on behalf of the minor person: I am the minor's: ☐ parent; ☐ legal guardian; OR ☐ managing conservator.

A physician has diagnosed the minor as suffering from a terminal or irreversible condition. I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Signature _____ Date _____

Printed name _____

TWO WITNESSES: (See qualifications on backside.) We have witnessed the above-noted competent adult person or authorized declarant making his/her signature above and, if applicable, the above-noted adult person making an OOH-DNR by nonwritten communication to the attending physician.

Witness 1 signature _____ Date _____ Printed name _____

Witness 2 signature _____ Date _____ Printed name _____

Notary in the State of Texas and County of _____. The above noted person personally appeared before me and signed the above noted declaration on this date: _____.

Courtesy of Texas Department of State Health Services.

local protocols and are aware of the specific restrictions these advance directives imply.

You may also encounter Physician Orders for Life-Sustaining Treatment (POLST) or Medical Orders for Life-Sustaining Treatment (MOLST) forms. These legal documents describe acceptable interventions for the patient in the form of medical orders and must be signed by an authorized medical provider to be valid. Be familiar with POLST or MOLST forms, and learn your local protocols and state laws with regard to withholding end-of-life medical interventions. If

you are presented with a POLST or MOLST form, then contact medical control for guidance.

In all other cases, begin CPR on anyone who is in cardiac arrest. It is usually impossible to know how long the patient's brain and vital organs have gone without oxygen. Factors such as air temperature and the basic health of the patient's tissues and organs can affect survivability. Most legal advisers recommend that, when in doubt, always give too much care rather than too little care. Always start CPR if any doubt exists.

Documentation and Communication

When you choose not to start CPR on a patient in cardiac arrest, you must ensure you are in compliance with local protocols and your documentation is detailed and accurate. Specifically, record signs from the physical exam that led to your decision and refer to the local protocol that states these signs as a reason not to start CPR. If extenuating circumstances such as entrapment physically prevent resuscitation attempts, then record the conditions thoroughly. These decisions occasionally give rise to questions that can often be settled immediately by reference to a well-written report.

When to Stop CPR

As an AEMT, you are generally not responsible for making the decision to stop CPR. After you begin CPR in the field, you must continue until one of the following events occurs (the STOP mnemonic):

- S** The patient *Starts* breathing and has a pulse.
- T** The patient's care is *Transferred* to another provider of equal or higher-level training.
- O** You are *Out of strength* or too tired to continue CPR.

P A *Physician* who is present or providing online medical direction assumes responsibility for the patient and directs you to discontinue CPR.

Out of strength does not merely mean weary; rather, it means you are no longer physically able to perform CPR. In short, always continue CPR until the patient's care is transferred to a physician or higher medical authority in the field. In some cases, your medical director or a designated medical control physician may order you to stop CPR on the basis of the patient's condition.

Words of Wisdom

Patients who do not achieve ROSC may be potential kidney or liver donors in select situations (eg, short transport times, rapid access to an organ recovery program). High-quality CPR maintains end organ perfusion. Follow your local protocols regarding the care of potential organ donors.

Every EMS system should have clear standing orders or protocols that provide guidelines for starting and stopping CPR. Your medical director and your system's legal adviser should agree on these

YOU are the Provider

Part 4

After 2 minutes of CPR, you reanalyze the patient's cardiac rhythm and receive a "no shock advised" message. The two EMTs immediately resume CPR. During CPR, your partner ventilates the patient with a bag-mask device and administers high-flow oxygen and considers insertion of an advanced airway. As the EMT who is ventilating the patient attempts to insert an oral airway, the patient starts to gag. You quickly reassess him.

Recording Time: 7 Minutes

Level of consciousness	Unresponsive
Respirations	Occasional agonal gasps; 4 breaths/min
Pulse	100 beats/min; strong carotid pulse; absent radial pulses
Skin	Skin color is improving
Blood pressure	70/40 mm Hg
Oxygen saturation (Spo₂)	82% (on oxygen)

8. How should you continue to treat this patient?
9. Because the patient is no longer in cardiac arrest, should you remove the AED pads? Why or why not?

protocols, which should be closely administered and reviewed by your medical director.

Foreign Body Airway Obstruction in Adults

Occasionally, a foreign body will be aspirated and block the upper airway. An airway obstruction may be caused by various factors, including relaxation of the throat muscles in an unresponsive patient, vomited or regurgitated stomach contents, blood, damaged tissue after an injury, dentures, or foreign bodies such as food or small objects.

Large objects that are visible but cannot be removed from the airway with suction, such as loose dentures, large pieces of food, or blood clots, should be swept forward and out with your gloved index finger. Suctioning can then be used as needed to keep the airway clear of thinner secretions such as blood, vomitus, and mucus.

Recognizing Foreign Body Airway Obstruction

An airway obstruction by a foreign body in an adult usually occurs during a meal. In children, it usually occurs during mealtime or at play. If the foreign body is not removed quickly, then the lungs will use up their oxygen supply, and unresponsiveness and death will follow. Management is based on the severity of the airway obstruction.

Mild Airway Obstruction

Patients with a mild (partial) airway obstruction are able to exchange adequate amounts of air, but still have signs of respiratory distress. Breathing may be noisy; however, the patient usually has a strong, effective cough. Leave these patients alone! Your main concern is to prevent a mild airway obstruction from becoming a severe (complete) airway obstruction. Abdominal thrusts are *not* indicated for patients with a mild airway obstruction.

For patients with a mild airway obstruction, first encourage them to cough or to continue coughing if they are already doing so. Do not interfere with the patient's own attempts to expel the foreign body. Instead, administer supplemental oxygen if needed and provide prompt transport to the ED. Closely monitor the patient and observe for signs of a severe airway obstruction (weak or absent cough, decreasing level of consciousness, cyanosis).

Controversies

Some organizations have suggested the initial use of back blows in adults with a foreign body airway obstruction and an ineffective cough. However, this recommendation is weak and supported by only low-certainty evidence. Some experts argue against the use of back blows in larger patients due to the simple impracticality of this procedure: The provider can hold an infant with the head downward while giving back blows, allowing gravity to help draw the object out of the airway. The provider cannot likely position an adult in an inverted position while giving back blows, meaning that as the back blows dislodge the object, gravity may pull it downward, deeper into the airway.

Always follow local protocols and contact medical control for direction when needed.

Responsive Patients

A sudden, severe airway obstruction is usually easy to recognize in someone who is eating or has just finished eating. The person is suddenly unable to speak or cough, grasps the throat, turns cyanotic, and makes exaggerated efforts to breathe. Either air is not moving into and out of the airway, or the air movement is so slight that it is not detectable. At first, the patient will be responsive and able to clearly indicate the problem. Ask the patient, "Are you choking?" The patient will usually respond by nodding yes. Alternatively, the patient may use the universal sign to indicate airway blockage (**FIGURE 15-30**).

FIGURE 15-30 Placing the hands at the throat is the universal sign to indicate choking.

© Jones & Bartlett Learning.

If there is a minimal amount of air movement, then you may hear a high-pitched sound called **stridor**. This occurs when the object is not fully blocking the airway, but the small amount of air entering the lungs is not enough to sustain life and the patient will eventually become unresponsive if the obstruction is not relieved.

Unresponsive Patients

When you discover an unresponsive patient, your first step is to determine whether the person is breathing and has a pulse. The unresponsiveness may be caused by airway obstruction, cardiac arrest, or many other conditions. If the patient has a pulse, but is not breathing, then you must make sure the airway is open and unobstructed.

You should suspect an airway obstruction if the standard maneuvers to open the airway and ventilate the lungs are ineffective. If you feel resistance when attempting to ventilate, then the patient probably has some type of obstruction. Reposition the airway and attempt to ventilate. If you still meet resistance, then follow the steps for removing a foreign body airway obstruction.

Removing a Foreign Body Airway Obstruction in an Adult

The manual maneuver recommended for removing severe airway obstructions in responsive adults and children older than 1 year is the **abdominal-thrust maneuver** (also called the Heimlich maneuver). This maneuver creates an artificial cough by causing a sudden increase in intrathoracic pressure when thrusts are applied to the subdiaphragmatic region; it is an effective method for removing a foreign body obstruction from the airway. If the patient with a severe airway obstruction is unresponsive, then perform chest compressions.

Responsive Patients

Abdominal-Thrust Maneuver

The goal of the abdominal-thrust maneuver is to compress the lungs upward and force residual air from the lungs to flow upward and expel the object. In responsive patients with a severe airway obstruction, repeat abdominal thrusts until the foreign body is expelled or the patient becomes unresponsive. Each thrust should be deliberate, with the intent of relieving the obstruction.

FIGURE 15-31 The abdominal-thrust maneuver in a responsive adult. Stand behind the patient and wrap your arms around the patient's abdomen. Place the thumb side of one fist against the patient's abdomen while holding your fist with your other hand. Press your fist into the patient's abdomen, using inward and upward thrusts.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

To perform abdominal thrusts on a responsive adult (**FIGURE 15-31**), do the following:

1. Stand behind the patient, and wrap your arms around their abdomen. Straddle your legs outside the patient's legs. This will allow you to easily slide the patient to the ground if they become unresponsive.
2. Make a fist with one hand; grasp the fist with the other hand. Place the thumb side of the fist against the patient's abdomen just above the umbilicus and well below the xiphoid process.
3. Press your fist into the patient's abdomen with a quick inward and upward thrust.
4. Continue abdominal thrusts until the object is expelled from the airway or the patient becomes unresponsive.

Chest Thrusts

You can safely perform the abdominal-thrust maneuver on all adults and children. However, for women in advanced stages of pregnancy and patients with obesity, use chest thrusts instead.

To perform chest thrusts on responsive pregnant adults and adults with obesity, do the following (**FIGURE 15-32**):

1. Stand behind the patient with your arms directly under the patient's armpits, and wrap your arms around the patient's chest.
2. Make a fist with one hand; grasp the fist with the other hand. Place the thumb side of the fist against the patient's sternum, avoiding the xiphoid process and the edges of the rib cage.

FIGURE 15-32 Remove a foreign body airway obstruction in a responsive pregnant adult using chest thrusts. Stand behind the patient and wrap your arms around the patient's chest. Place the thumb side of one fist against the chest while holding your fist with your other hand. Press your fist into the patient's chest with backward thrusts.

© Jones & Bartlett Learning.

3. Press your fist into the patient's chest with backward thrusts until the object is expelled or the patient becomes unresponsive.
4. If the patient becomes unresponsive, then begin CPR, starting with chest compressions (**FIGURE 15-33**).

Words of Wisdom

If a responsive choking patient is found lying on the floor, then administer abdominal thrusts by straddling the patient's legs, place your hands just above the umbilicus, and give rapid thrusts inward and upward under the rib cage, using the heel of your hand with your other hand on top of it.

FIGURE 15-33 An unresponsive patient with a foreign body airway obstruction requires cardiopulmonary resuscitation.

© Jones & Bartlett Learning.

Responsive Patients Who Become Unresponsive

A patient with a foreign body airway obstruction may become unresponsive while you are attempting to remove the obstruction. In this case, begin CPR, starting with chest compressions. Follow these steps to manage the patient's foreign body airway obstruction:

1. Carefully support the patient to the ground and immediately call for help (or send someone to call for help).
2. Perform 30 chest compressions, using the same landmark as you would for CPR (center of the chest, between the nipples). Do not check for a pulse before performing chest compressions.
3. Open the airway and look in the mouth. If you see an object that can easily be removed, then remove it with your fingers and attempt to ventilate. If you do not see an object, then resume chest compressions.
4. Repeat steps 2 and 3 until the obstruction is relieved or paramedics take over.

If you are able to, remove an object from the mouth, then attempt to ventilate. If ventilation produces chest rise, then continue to ventilate and check for a pulse. If a pulse is present but the patient is not breathing, then continue rescue breathing and monitor the pulse. If a pulse is absent, then

continue CPR (compressions and ventilations) and apply the AED as soon as it is available.

Unresponsive Patients

When a patient is found unresponsive, it is unlikely you will know what caused the problem. Begin CPR by determining unresponsiveness and checking for breathing and a pulse. If a pulse is present but breathing is absent, open the airway and attempt to ventilate. If the first ventilation does not produce visible chest rise, reposition the airway and reattempt to ventilate. If both ventilation attempts do not produce visible chest rise, perform 30 chest compressions, and then open the airway and look in the mouth. If an object is visible and can easily be removed, remove it with your fingers and attempt to ventilate. Never perform blind finger sweeps on any patient; doing so may push the obstruction farther into the airway. If an object is not visible or cannot easily be removed, then resume chest compressions. Continue the sequence of chest compressions, open the airway, and look inside the mouth until the airway is clear or paramedics arrive.

Foreign Body Airway Obstruction in Infants and Children

As mentioned previously, airway obstruction is common in infants and children, usually caused by a foreign body (such as food or a toy) or by an infection, resulting in swelling and narrowing of the airway. Try to identify the cause of the obstruction as soon as possible. In patients who have signs and symptoms of an airway infection, do not waste time trying to dislodge a foreign body. Administer supplemental oxygen if needed and immediately transport the child to the ED.

A previously healthy child who is eating or playing with small toys or an infant who is crawling about the house and who suddenly has difficulty breathing has probably aspirated a foreign body. As in adults, foreign bodies may cause a mild or a severe airway obstruction.

With a mild airway obstruction, the child can cough forcefully, although they may be wheezing between coughs. As long as the patient can breathe, cough, or talk, do not interfere with their attempts

YOU are the Provider

Part 5

You package the patient, load him into the ambulance, and begin transport to a hospital located 5 miles away. An EMT from the backup ambulance accompanies you in the back and continues rescue breathing. En route, you reassess the patient and establish an 18-gauge IV line in his left antecubital fossa with normal saline running wide open. Next, you call in your radio report to the receiving hospital.

Recording Time: 12 Minutes

Level of consciousness	Unresponsive
Respirations	8 breaths/min; shallow depth
Pulse	94 beats/min; strong carotid pulse, weak radial pulses
Skin	Cool and dry
Blood pressure	86/66 mm Hg
Oxygen saturation (SpO₂)	95% (on oxygen)

- 10.** Would an ITD benefit your patient at this point?
- 11.** What further treatment, if any, is indicated for this patient?
- 12.** What options do you have if you are unable to obtain IV access?

to expel the foreign body. As with the adult, encourage the child to continue coughing. Administer supplemental oxygen if needed (and tolerated), and provide transport to the ED.

Intervene only if signs of a severe airway obstruction develop, such as a weak, ineffective cough; cyanosis; stridor; absent air movement; or a decreasing level of consciousness.

Removing a Foreign Body Airway Obstruction in a Child

Responsive Child

If you determine a child older than 1 year has an airway obstruction, stand or kneel behind the child and provide abdominal thrusts in the same manner as an adult, but use less force, until the object is expelled or the child becomes unresponsive. If the child becomes unresponsive, follow the same steps as for the unresponsive adult.

To perform the abdominal-thrust maneuver in a responsive child who is in a standing or sitting position, follow these steps (**FIGURE 15-34**):

FIGURE 15-34 To perform the abdominal-thrust maneuver on a child, kneel on one knee behind the child, wrap your arms around the child's body, and place your fist just above the umbilicus and well below the lower tip of the sternum.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

1. Kneel on one knee behind the child, and circle both of your arms around the child's body. Prepare to give abdominal thrusts by placing your fist just above the patient's umbilicus and well below the xiphoid process. Place your other hand over that fist.
2. Give the child abdominal thrusts in an upward direction. Avoid applying force to the lower rib cage or sternum.
3. Repeat this technique until the child expels the foreign body or becomes unresponsive.
4. If the child becomes unresponsive, position the child on a firm, flat surface and immediately call for help (or send someone to call for help). Follow the steps for managing an unresponsive child discussed in the following section.

Controversies

As described previously for adults who have a foreign body airway obstruction and an ineffective cough, some organizations have suggested the initial use of back blows in children older than 1 year. Again, always follow local protocols and contact medical control for direction when needed.

Unresponsive Child

If a child older than 1 year with an airway obstruction becomes unresponsive, the child is managed in the same manner as an adult. **SKILL DRILL 15-6** demonstrates the steps for removing a foreign body airway obstruction in an unresponsive child. If you manage to clear the airway obstruction in an unresponsive child but they still have no spontaneous breathing or circulation, then perform CPR (compressions and ventilations) and apply the AED as soon as it is available.

Removing a Foreign Body Airway Obstruction in Infants

Responsive Infants

Do not use abdominal thrusts on a responsive infant with a foreign body airway obstruction because of the risk of injury to the immature organs of the abdomen. Instead, perform back blows and chest

Skill Drill 15-6 Removing a Foreign Body Airway Obstruction in an Unresponsive Child

Step 1

Take standard precautions. Carefully place the child in a supine position on a firm, flat surface.

Step 2

Perform 30 chest compressions (15 compressions if two rescuers are present) using the same landmark as you would for CPR (lower half of the sternum). Do not check for a pulse before performing chest compressions.

Step 3

Open the airway and look inside the mouth.

Step 4

If an object is visible and can easily be removed, then remove it with your fingers and attempt to ventilate.

Step 5

If you do not see an object in the mouth, then resume chest compressions. Continue the sequence of chest compressions, opening the airway, and looking inside the mouth until the obstruction is relieved or the patient is transferred to a higher level of care.

**A****B**

FIGURE 15-35 **A.** Hold the infant facedown with the body resting on your forearm. Support the jaw and face with your hand, and keep the head lower than the rest of the body. Give the infant five back blows between the shoulder blades, using the heel of your hand. **B.** Give the infant five quick chest thrusts, using two fingers placed on the lower half of the sternum.

© Jones & Bartlett Learning.

thrusts to try to clear a severe airway obstruction in a responsive infant, as follows (**FIGURE 15-35**):

1. Hold the infant facedown, with the body resting on your forearm. Support the infant's jaw and face with your hand, and keep the head lower than the rest of the body.
2. Deliver five back blows between the shoulder blades, using the heel of your hand.
3. Place your free hand behind the infant's head and back, and turn the infant faceup on your other forearm and thigh, sandwiching the infant's body between your two hands and arms. The infant's head should remain below the level of the body.
4. Give five quick chest thrusts in the same location and manner as chest compressions, using two fingers placed on the lower half of the sternum. For larger infants, or if you have small hands, you can perform this step by placing the infant in your lap and turning the infant's whole body as a unit between back blows and chest thrusts.
5. Check the airway. If you can see the foreign body, then remove it. If you do not see a foreign body, repeat the cycle as often as necessary.
6. If the infant becomes unresponsive, then begin CPR and follow the same sequence as for a child and adult.

Unresponsive Infants

If the infant becomes unresponsive during your attempts to relieve an airway obstruction, then perform CPR starting with chest compressions. Do not check for a pulse before starting compressions. Open the airway and look in the mouth. If you see an object that can easily be removed, then remove it with your finger and attempt to ventilate. If you do not see an object, then resume chest compressions. Continue the sequence of chest compressions, open the airway, and look inside the mouth until the obstruction is relieved or paramedics take over.

Special Resuscitation Circumstances

Opioid Overdose

An opioid is a narcotic drug that, when taken in excess, depresses the central nervous system and causes respiratory arrest followed by cardiac arrest. Examples of opioids include heroin and oxycodone. For situations in which opioid overdose is the suspected cause of a patient's cardiac arrest, bystanders may have administered the antidote naloxone (Narcan) to the patient prior to EMS arrival. Naloxone blocks opiate receptors in the body and reverses the effect of opioid overdose. Naloxone auto-injector devices or nasal atomizers, intended for use by laypeople (as well as health care providers), are now available in the United States. If you respond to a patient who has possibly overdosed on an opioid and naloxone was administered by a bystander prior to your arrival, then determine how

much of the medication was given and the route by which it was given.

As an AEMT, naloxone is one of the medications that you can administer through local protocols written by your EMS medical director in cases of suspected opioid overdose. The recommended algorithm for implementing naloxone into the cardiac arrest management sequence is discussed in Chapter 23, *Toxicology*.

Standard resuscitation measures (ie, high-quality chest compressions, ventilation, defibrillation) take priority over naloxone administration; do not delay other interventions while awaiting the patient's response to naloxone therapy. Many patients who have overdosed on an opioid have a pulse (although slow) but are not breathing. In these patients, bag-mask ventilation is the most critical treatment, followed by administration of naloxone if it is available.

Cardiac Arrest in Pregnancy

If you encounter a pregnant patient who is in cardiac arrest, your priorities are to provide high-quality CPR and relieve pressure on the aorta and vena cava. When the patient lies supine, the pregnant uterus can compress the aorta and inferior vena cava (aortocaval compression). Compression of the inferior vena cava causes a significant decrease in blood return to the heart and a secondary decrease in the forward flow of blood to the vital organs.

If the pregnant patient is not in cardiac arrest, then position the patient on the left side to relieve pressure on the great vessels. However, if the patient is in cardiac arrest, this approach is impractical, because the patient must remain in a supine position to maximize the effectiveness of compressions. Therefore, if the top of the patient's uterus (fundus) can be felt at or above the level of the umbilicus, perform manual displacement of the uterus to the patient's left to relieve aortocaval compression while CPR is being performed. This step will improve the effectiveness of compressions (**FIGURE 15-36**).

Grief Support for Family Members and Loved Ones

Whenever you assist a patient, remember that the patient's loved ones may also be affected by the emergency. Serious illness, injury, and pediatric

FIGURE 15-36 Manual left displacement of the uterus. The two-handed technique is shown. Alternatively, one hand can be used.

© Jones & Bartlett Learning.

patients create an especially high level of anxiety for family members. A health emergency is often hard for family members to understand. In some cases, family members may experience a psychological crisis that turns into a medical crisis and may become patients themselves.

Consider the scenario of a cardiac arrest in an otherwise healthy 57-year-old man. The family is watching your team perform CPR. Family members may assume you will bring him back or, at the very least, will expect you to transport. After 30 minutes or so, you stop resuscitation and start packing up your gear, then turn the scene over to the police. The patient is lying dead on the floor.

A trend in cardiac arrest care is to stay on the scene and perform the entire resuscitation in the location where the patient was found, particularly when ALS care is provided at the scene. Many EMS systems advocate this practice because continuous compressions are an important part of an effective resuscitation effort. CPR in the back of an ambulance is generally not as effective. If the patient has not responded to treatment after 20 to 30 minutes (or longer), many protocols suggest discontinuing resuscitation efforts and not transporting. However, this may create an uncomfortable situation at the scene.

For EMS crews, wanting to help but not knowing what to do can be very stressful. Is it the responsibility of EMS to explain the death to the family? Would you consider the bereaved widow the legal or moral responsibility of EMS? How is good patient care defined here? If you consider a spouse and

perhaps other family members to be your patients as well, then it is appropriate to interact with them. Using the above scenario as an example, consider the following things that may make grief support in the field a little easier.

Whereas this cardiac arrest may be one of many similar calls in your career, family members and loved ones will remember this event in detail for the rest of their lives. Your reaction to them will form a lasting impression. Conversely, a mismanaged death notification or poor interaction could leave the family feeling disrespected or ignored. A compassionate and sensitive approach will leave a positive impression of you and your agency. Most important, appropriate and supportive care at the onset of grief may positively affect the family's grieving process.

Families do not typically expect EMS providers to stop resuscitation and leave their loved one on scene. When death appears imminent and resuscitation efforts are unsuccessful, make the family members aware the patient is not responding to treatment. Discuss with them what is happening so they may be better prepared for the inevitable. Keep family members informed throughout the resuscitation process because it may also help them feel more in control.

Sequential notification starts during resuscitation efforts; family members should be updated as the resuscitation progresses, if possible. Designate one provider to communicate the patient's status to family members, so information is streamlined from one source rather than from multiple providers. Be concise and clear. For example, say, "Your husband is not breathing and his heart has stopped. We are attempting to restart his heart." After resuscitation efforts have stopped, it is appropriate to tell them, "As you know, when we arrived, your husband wasn't breathing and did not have a pulse. He has not responded to any of our treatments. I'm sorry, but he has died." Avoid euphemisms such as "passed away" or "passed on," because these expressions may be confusing or misinterpreted. Law enforcement personnel may be involved in the official death declaration and will likely be responsible for what happens next, such as determining whether the medical examiner should be notified.

In a situation where ROSC occurs prior to transport, family members may wish to interact with the patient. This can give them comfort, especially if the patient ultimately does not survive.

After resuscitation has stopped, these other measures can be helpful:

- Take the family to a quiet, private place.
- Introduce yourself and anyone with you.
- Use clear language and speak in a warm, sensitive, and caring manner.
- Try to exhibit calm, reassuring authority.
- Use the patient's name.
- Use eye contact and appropriate touch.
- Expect family members to show emotion as they begin the grieving process. Be prepared for different reactions, including anger.
- Although you are still on scene, be supportive but do not hover.
- Ask if a friend or family member can be called to come and help support them.
- When you need to leave, turn over the family to someone else, for example, a police officer.

Some family members will want to see the deceased. Being able to touch or talk to their loved ones may be helpful to them. This may not be advisable in a medical examiner's case. Law enforcement personnel will make that determination. It is appropriate to make the body presentable, but follow local protocols regarding movement of the patient or removal of resuscitation equipment.

Another consideration is to ensure children are not ignored. They may not understand death. Preschool-age children may be less affected, whereas older children understand death but do not expect it to happen to someone they know. Younger children tend to blame themselves. Teenagers may be highly affected but may mask their feelings.

It is never easy to be the bearer of bad news, but it can help to know you did your best for the family during a difficult situation. Lastly, consider your own feelings in this stressful situation and make sure you seek assistance if needed. See Chapter 2, *Workforce Safety and Wellness*, for a discussion of the emotional aspects of emergency care and stress management.

Education and Training for the AEMT

You may go weeks or months without performing CPR on a human, depending on how busy your EMS system is. Like any skill, CPR skills can deteriorate over time. Practice this skill often using

manikin-based training—ideally, more frequently than the standard recertification that occurs every 2 years.

You are encouraged to use high-fidelity manikins for CPR training, if your system's budget allows. If this is not an option, then CPR devices that provide corrective feedback are preferred over devices that provide only voice prompts (ie, a metronome).

CPR self-instruction through videos and/or computer-based modules with hands-on practice may be a reasonable alternative to instructor-led courses, because it may facilitate frequent retraining.

Education and Training for the Public

As an AEMT, you are a patient advocate. You are not only responsible for providing the best possible care for your patient, but you must also do your part to facilitate the training of laypeople in the critical skills of CPR and AED operation. Training in CPR

and AED usage should not be limited to health care providers. Not enough laypeople are trained to perform these life-saving skills. Ask yourself, “Who is the *real* first responder?” Obviously, the layperson is likely to be at the scene before you and your team arrive.

As discussed previously, many laypeople assume CPR requires both mouth-to-mouth rescue breathing and chest compressions. As long as this misconception remains, fewer people will be willing to help during an emergency, which means fewer lives will be saved. If you are asked to train members of your community how to perform compression-only CPR, then you should consider it your professional responsibility and be willing to assist.

It is likely that some citizens in your service area are at increased risk for cardiac arrest. Your agency should make an effort to identify these potential patients and educate their families to recognize cardiac arrest and to train them to perform compression-only CPR.

YOU are the Provider SUMMARY

1. What should you immediately do on receiving this update from dispatch?

After you are informed that CPR is in progress, you should immediately request additional assistance. Effective treatment of a patient in cardiac arrest requires adequate personnel at the scene and during transport. As an AEMT, familiarize yourself with the resources that are available to you and know when it is appropriate to request them.

The type of backup you receive (ie, BLS versus paramedic) will depend on your EMS system and the resources that are available to you. High-quality CPR and defibrillation, combined with early advanced care, increase the patient's chance for survival.

If you do not have access to other AEMTs or to paramedics, then request assistance from the fire department. Fire departments are often staffed with at least one or two emergency medical responders who are able to perform CPR and assist with certain BLS interventions.

Regardless of the resources available to you, request them as soon as possible—in this case, as soon as you are advised CPR is in progress. One AEMT cannot effectively treat a cardiac arrest patient during transport; you would have to perform continuous CPR while your partner drives the ambulance (or vice versa), which could result in rescuer fatigue and decreased effectiveness of chest compressions.

2. What should be your initial actions on arriving at this scene?

After you ensure your safety, approach this patient as you would any other patient, by performing a primary survey. Although the dispatcher has advised you that bystander CPR is in progress, you must still assess the patient to confirm he is indeed apneic and pulseless and requires CPR.

Your primary survey should take only a few seconds, just long enough to confirm the patient is in cardiac arrest. If he is in cardiac arrest, then begin CPR immediately, apply the AED as soon as it is available, and analyze the patient's cardiac rhythm. To avoid interrupting CPR, you should apply the AED pads around your partner's hands as your partner is performing chest compressions (do not stop compressions to do this).

If the AED advises you to shock, then deliver the shock and immediately resume CPR, starting with chest compressions. If the AED does not advise you to shock, then immediately resume CPR, starting with chest compressions. During CPR, ask the two bystanders if they witnessed the event and determine whether they know anything about the patient (ie, past medical history, events leading up to the arrest).

Regardless of how a call is dispatched and whether or not you assume assistance with patient

YOU are the Provider SUMMARY *continued*

care from bystanders or other health care providers, it is important for you to always perform a primary survey of the patient.

3. What links in the chain of survival have been maintained at this point?

The following links in the chain of survival have been maintained:

- Recognition and activation of the emergency response system, because the bystanders quickly recognized the patient was experiencing a cardiac emergency and immediately called 9-1-1.
- Immediate, high-quality CPR, because the bystanders began CPR directly after calling 9-1-1.
- Basic and advanced EMS, because EMS providers are at the scene providing specialized care to the patient.

The following links in the chain of survival have not been maintained:

- Rapid defibrillation, because it has not yet occurred. Of all the links in the chain of survival, early defibrillation has the most profound impact on patient survival. With early access and early CPR, defibrillation may successfully terminate lethal cardiac dysrhythmias in a significant number of patients. For each minute that defibrillation is delayed, the patient's chance for survival decreases by 7% to 10%.
- ALS and postarrest care, because ROSC has not been established and the patient has not arrived at the hospital.
- Recovery, which may be an ongoing process for the patient and family.

4. Why is it so crucial to minimize interruptions in CPR?

Even when CPR is performed correctly (that is, at a rate of 100 to 120 compressions per minute and a depth of 2 to 2.4 inches [5 to 6 cm] in the adult), chest compressions deliver only about one-third of a person's normal cardiac output. When CPR is performed properly and with minimal interruption, it is often enough to keep the patient's vital organs viable until defibrillation and more advanced care can be provided at the ED. Of course, this assumes that defibrillation and advanced care are provided within a short period of time.

Within a few seconds of stopping chest compressions, the pressure generated in the arteries drops to near zero; therefore, frequent or prolonged interruptions in chest compressions will not even provide the

minimum perfusion needed to keep the vital organs viable. This has been clearly linked to low survival rates from cardiac arrest. Remember to maintain a chest compression fraction of at least 60%.

As soon as cardiac arrest has been confirmed, it is crucial to begin CPR immediately and apply the AED as soon as it is available. Even when the AED pads are being applied, your partner should continue chest compressions; you should apply the pads around your partner's hands.

5. Should you remove the medication patch or leave it in place? Why or why not?

The patch is located on the patient's right upper chest, which is where you will place one of the AED pads. Because of its location, the patch could interfere with the electrical current to the heart and may cause burns to the patient's skin. To prevent this complication, remove the patch with a gloved hand, wipe any residue from the skin, and then apply the AED pads.

6. What does the bulge and scar over the patient's left chest indicate? How will this affect the way you treat the patient?

A hard lump or bulge on the patient's chest, usually with a corresponding scar, indicates an AICD or pacemaker. These devices are used in patients who are at high risk for certain cardiac dysrhythmias and cardiac arrest. The AICD will deliver shocks directly to the heart if it detects a lethal cardiac dysrhythmia. Implanted pacemakers are used to increase the patient's heart rate if it falls below a given value.

If the AED pads are placed directly over the device, then shocks delivered by the AED may be less effective. Therefore, if you identify an AICD or pacemaker, place the AED pad at least 1 inch (2.5 cm) away from the device. Because most of these devices are implanted in the upper left chest, this should not be an issue. The pads are placed to the right of the upper sternum and to the lower left chest, just below the nipple, so they should be well beyond 1 inch (2.5 cm) from the device. Follow your local protocols regarding patients with AICDs or implanted pacemakers.

7. Which rhythms will the AED defibrillate?

AEDs are designed to shock VF and pulseless VT. It is important to remember AEDs will not shock all cardiac rhythms, just lethal ventricular rhythms. However, remember an AED cannot detect the presence of a pulse and may shock a patient in VT who has a pulse. This is why you should not apply the AED to a patient with a pulse.

YOU are the Provider SUMMARY *continued***8. How should you continue to treat this patient?**

You have restored a pulse in your patient; however, his breathing is not adequate. Agonal gasps are ineffective and do not produce adequate minute volume.

Some patients may have an intact gag reflex, despite being unresponsive; in these cases, an oropharyngeal airway is contraindicated. Insert a nasopharyngeal (nasal) airway and continue to provide rescue breathing. Deliver one breath every 6 seconds (10 breaths/min); each breath should be delivered over 1 second (just enough to produce visible chest rise). Closely and carefully monitor the patient's pulse and be prepared to resume CPR if necessary.

Assume the patient has a full stomach and have a suction unit ready in case he regurgitates. Remember, mortality increases significantly if aspiration occurs. It is also important to avoid hyperventilating the patient.

9. Because the patient is no longer in cardiac arrest, should you remove the AED pads? Why or why not?

Although the patient is not in cardiac arrest, he is still at high risk for redeveloping cardiac arrest. Therefore, do not remove the AED pads; simply continue rescue breathing, and prepare the patient for prompt transport.

10. Would an ITD benefit your patient at this point?

An ITD is a valve device that is placed between the ET tube and resuscitation bag; it can also be placed in between the resuscitation bag and mask if the patient is not intubated. It is used only for patients who are apneic and pulseless. At this point, your patient has a pulse and is breathing (albeit slowly and shallowly); therefore, the ITD is not indicated. Furthermore, the ITD may be of benefit when used during active compression-decompression CPR, but it is not recommended for use during conventional CPR. If ROSC occurs, the ITD must be removed.

11. What further treatment, if any, is indicated for this patient?

Further treatment of your patient should consist of careful monitoring because he remains at high risk for recurrence of cardiac arrest. In patients who are responsive and alert, the presence of a pulse is obvious; however, when a patient is unresponsive, you must frequently reassess for a pulse.

Unresponsive patients are at an increased risk for regurgitation, which could lead to aspiration and increased mortality. Vigilantly monitor the patient's airway status and be prepared to turn his head to the side if he regurgitates. Maintain his airway with manual positioning and a basic airway adjunct, in this case, a nasal airway.

Although the patient is breathing, his breaths are slow and shallow. Slow, shallow (reduced tidal volume) respirations will not produce adequate minute volume; therefore, continue to assist the patient's ventilations with a bag-mask device, but do not hyperventilate him. Deliver each breath over 1 second while observing for visible chest rise. Monitor his oxygen saturation (SpO₂) level and heart rate to help you determine if your assisted ventilations are adequate.

As mentioned earlier, do not remove the AED pads. Turn off the AED, but be prepared to stop the ambulance if cardiac arrest redevelops.

The patient's blood pressure (86/66 mm Hg) is still low. Follow your local protocols regarding positioning of the patient to improve his blood pressure.

12. What options do you have if you are unable to obtain IV access?

You have limited options if you are unsuccessful at obtaining IV access. In the setting of a cardiac arrest, you should limit yourself to two attempts to gain IV access, prior to obtaining IO access.

Narrative

EMS dispatched to local farmer's market for "CPR in progress." On arrival at the scene, found two bystanders performing CPR on the patient, a 48-year-old male. Medic 22 (BLS) was dispatched to the scene to assist. Primary survey revealed that the patient was apneic and pulseless. Continued two-rescuer CPR for 2 minutes while the AED was being prepared. Per one of the bystanders, the patient delivered a load of produce then sat down in his truck and slumped over the steering wheel. There was no trauma involved. The bystander further stated that by the time he got to the patient, he was unresponsive, apneic, and pulseless. After 2 minutes of CPR, EMS analyzed patient's cardiac rhythm with the AED and received a shock advised message. Delivered single shock and immediately resumed CPR. Medic 22 arrived at scene and assisted with CPR and airway management. The patient's past medical history was unknown, although he had an AICD and was wearing a medication patch, which was removed. Continued CPR for 2 minutes, reanalyzed the patient's cardiac rhythm, and received a no shock advised message. Continued CPR and attempted to insert an oral airway; however, the patient began to gag. Immediate reassessment revealed that he had a strong carotid pulse, but was not breathing adequately. Inserted a nasal airway, continued ventilations at 10 breaths/min, packaged the patient, and loaded him into the ambulance. EMT Smith from Medic 22 assisted with patient care en route to the hospital. En route, reassessed patient and found that he remained unresponsive; his respiratory rate increased, but the depth of his breathing remained shallow. Established an 18-gauge IV left AC with NS wide open to give a 20 mL/kg bolus. Continued assisted ventilation and called in radio report to the receiving facility. Monitored the patient's pulse, provided additional supportive care, and delivered him to the ED without incident. Gave verbal report to attending physician. Cleared the hospital and returned to service at 1528.

End of report

Prep Kit

Ready for Review

- BLS is noninvasive, emergency life-saving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.
- BLS care focuses on the ABCDEs: airway (obstruction), breathing (respiratory arrest), circulation (cardiac arrest or severe bleeding), disability (brief neurologic evaluation), and exposure (adequate exposure of each area being examined). If the patient is in cardiac arrest, then use a CABDE sequence (compressions, airway, breathing, disability, exposure).
- CPR is used to establish artificial ventilation and circulation in a patient who is not breathing and has no pulse.
- The goal of CPR is to help restore spontaneous breathing and circulation; however, advanced procedures such as medications and defibrillation are often necessary for this to occur.

- ALS involves advanced life-saving procedures, such as cardiac monitoring, administering IV fluids and medications, and using advanced airway adjuncts.
- The six links in the chain of survival are (1) recognition and activation of the emergency response system; (2) immediate, high-quality CPR; (3) rapid defibrillation; (4) basic and advanced EMS; (5) ALS and postarrest care; and (6) recovery.
- Apply an AED to any nontrauma cardiac arrest patient as soon as it is available.
- When using an AED on a child between ages 1 and 8 years, use pediatric-size pads and a dose-attenuating system (energy reducer). If these items are unavailable, then use adult-size AED pads. In infants (age 1 month to 1 year), manual defibrillation is preferred. If a manual defibrillator is unavailable, then use an AED equipped with pediatric-size pads and a dose attenuator. If neither option is available, then use adult-size AED pads.
- As an AEMT, it is your responsibility to start CPR in virtually all patients who are in cardiac arrest. The three general exceptions to the rule are as follows: (1) do not start CPR if the scene is unsafe, (2) do not start CPR if the patient has obvious signs of death, and (3) do not start CPR if the patient and their physician have a previously agreed-on DNR or no-CPR order.
- As an AEMT, you are generally not responsible for making the decision to stop CPR. After you begin CPR in the field, you must continue until one of the following events occurs (the STOP mnemonic):
 - **S**, the patient *Starts* breathing and has a pulse.
 - **T**, the patient's care is *Transferred* to another provider of equal or higher-level training.
 - **O**, you are *Out* of strength or too tired to continue.
 - **P**, a *Physician* who is present or providing online medical direction assumes responsibility for the patient and gives direction to discontinue CPR.
- An airway obstruction may have various causes, including relaxation of the throat muscles in an unresponsive patient, vomited or regurgitated stomach contents, blood, damaged tissue after an injury, dentures, or foreign bodies such as food or small objects.
- The manual maneuver recommended for removing severe airway obstructions in the responsive adult and child is the abdominal-thrust maneuver (the Heimlich maneuver). Use back blows and chest thrusts to treat a responsive infant with a severe airway obstruction.
- If the adult, child, or infant with a severe airway obstruction is unresponsive, then perform CPR, starting with chest compressions.
- As an AEMT, you will encounter situations in which grief support for family and loved ones will be part of your role. After resuscitation has stopped, turn your attention to the family and loved ones, and provide clear communication and emotional support.

Vital Vocabulary

abdominal-thrust maneuver The preferred method to dislodge a severe airway obstruction in adults and children; also called the Heimlich maneuver.

active compression-decompression CPR A technique that involves compressing the chest and then actively pulling it back up to its neutral position or beyond (decompression); may increase the amount of blood that returns to the heart and, thus, the amount of blood ejected from the heart during the compression phase.

advanced life support (ALS) Advanced life-saving procedures used to treat medical conditions,

such as cardiac monitoring, administration of intravenous fluids and medications, and the use of advanced airway adjuncts. EMTs and AEMTs may be trained in some of these areas.

basic life support (BLS) Noninvasive, emergency life-saving care used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.

cardiopulmonary resuscitation (CPR) The combination of chest compressions and rescue breathing used to establish adequate ventilation and circulation in a patient who is not breathing and has no pulse.

chest compression fraction The total percentage of time during a resuscitation attempt in which active chest compressions are being performed.

crew resource management (CRM) A way for team members to work together with the team leader to develop and maintain a shared understanding of the emergency situation; to collaborate and communicate, fulfill their roles and responsibilities, and achieve the shared goal of the best possible patient outcome.

dependent lividity Blood settling to the lowest point of the body, causing discoloration of the skin; a definitive sign of death.

gastric distention A condition in which air fills the stomach, often as a result of high volume and pressure during artificial ventilation.

head tilt–chin lift maneuver A combination of two movements to open the airway by tilting the forehead back and lifting the chin; not used for trauma patients.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal; may lead to increased intrathoracic pressure, decreased venous return, and hypotension when associated with bag-mask device use.

impedance threshold device (ITD) A valve device placed between the endotracheal tube and a bag-mask device that limits the amount of air entering the lungs during the recoil phase between chest compressions.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially

reversible because permanent injury has not yet occurred.

jaw-thrust maneuver Technique to open the airway by placing the fingers behind the angle of the jaw and bringing the jaw forward; used for patients who may have a cervical spine injury.

load-distributing band (LDB) A circumferential chest compression device composed of a constricting band and backboard that is either electrically or pneumatically driven to compress the heart by putting inward pressure on the thorax.

mechanical piston device A device that depresses the sternum via a compressed gas-powered or electric-powered plunger mounted on a backboard.

recovery position A side-lying position used to maintain a clear airway in unresponsive patients who are breathing adequately and do not have suspected injuries to the spine, hips, or pelvis.

return of spontaneous circulation (ROSC) The return of a pulse and effective blood flow to the body in a patient who previously was in cardiac arrest.

rigor mortis Stiffening of the body muscles caused by chemical changes within muscle tissue; a definitive sign of death.

stridor A harsh, high-pitched respiratory sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

ventilation The exchange of air between the lungs and the air of the environment, spontaneously by the patient or with assistance.

Chapter 16

Medical Overview

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Medical Overview

Assessment and management of a

- Medical complaint (pp 856–859)

Pathophysiology, assessment, and management of medical complaints to include

- Transport mode (pp 859–861)
- Destination decisions (pp 861–862)

Infectious Diseases

Awareness of

- A patient who may have an infectious disease (p 862)

Assessment and management of

- A patient who may have an infectious disease (pp 862–863)
- A patient who may be infected with a bloodborne pathogen (p 863)
 - Human immunodeficiency virus (HIV) (pp 863–864)
 - Hepatitis B (p 866)
- Antibiotic-resistant infections (p 870)
- Current infectious diseases prevalent in the community (pp 871–872)

KNOWLEDGE OBJECTIVES

1. Differentiate between medical emergencies and trauma emergencies, remembering that some patients may have both. (p 855)
2. Name the various categories of common medical emergencies and give examples. (pp 855–856)
3. Describe the evaluation of the nature of illness. (p 856)
4. Identify elements and steps in the assessment of a patient with a medical emergency. (pp 856–859)
5. Explain the importance of transport time and destination selection for a medical patient. (pp 859–862)
6. Describe the general assessment and management principles when working with a patient who may have an infectious or communicable disease. (pp 862–863)
7. Define epidemic and pandemic. (p 863)
8. Discuss the pathophysiology, signs and symptoms, and management of a patient with HIV or acquired immunodeficiency syndrome. (pp 863–865)
9. Discuss precautions to protect against exposure to HIV. (pp 864–865)
10. Discuss the pathophysiology, signs and symptoms, and management of a patient with

- influenza, and describe ways to protect against its transmission. (p 865)
11. Discuss the pathophysiology, signs and symptoms, and management of a patient with hepatitis. (pp 865–868)
 12. Discuss precautions to protect oneself against exposure to hepatitis. (p 868)
 13. Discuss other infectious diseases of special concern and their routes of transmission, including herpes simplex, syphilis, meningitis, tuberculosis, pertussis, and methicillin-resistant *Staphylococcus aureus*. (pp 868–870)
 14. Identify other new and emerging diseases, including West Nile virus, severe acute respiratory syndrome, and avian flu. (pp 870–871)
 15. Discuss infections that are global health issues, including Middle East respiratory syndrome coronavirus, COVID-19, and Ebola. (pp 871–873)
 16. Understand the procedure for taking a travel history, and apply its findings to the patient's present condition. (p 874)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

Patients who need emergency medical services (EMS) assistance generally have experienced either a medical emergency or trauma emergency; in some cases, both have occurred. **Trauma emergencies** involve injuries resulting from physical forces applied to the body. **Medical emergencies** involve illnesses or conditions caused by disease. Although it is important for you to be able to make the distinction between medical and trauma patients, it is equally important for you to remember that patients may have a combination of medical and trauma conditions affecting their health. For example, a person who has a heart attack while driving may be involved in a crash, or a diabetic patient whose blood glucose level is too low may fall and be injured. This chapter discusses medical emergencies. Chapter 26, *Trauma Overview*, discusses trauma emergencies.

Words of Wisdom

Patients are classified as critical or stable based on their presentation, not based on whether they have a medical illness or a traumatic injury. A myocardial infarction is a critical medical condition, whereas an isolated broken toe is a stable traumatic injury.

Types of Medical Emergencies

There are many types of medical emergencies (**TABLE 16-1**). Respiratory emergencies occur when patients have trouble breathing or when the

TABLE 16-1 Common Medical Emergencies

Type of Medical Emergency	Examples of Conditions
Respiratory	Asthma, emphysema, chronic bronchitis
Cardiovascular	Myocardial infarction, heart failure
Neurologic	Seizure, stroke, syncope
Gastrointestinal	Appendicitis, diverticulitis, pancreatitis
Urologic	Kidney stones, pyelonephritis
Endocrine	Diabetes mellitus
Hematologic	Sickle cell disease, hemophilia
Immunologic	Anaphylactic reaction (severe allergy to bee stings, food, or other substances)
Toxicologic	Substance abuse; food, plant, or chemical poisoning
Psychiatric	Alzheimer disease, schizophrenia, depression
Gynecologic	Vaginal bleeding, sexually transmitted disease, pelvic inflammatory disease, ectopic pregnancy

© Jones & Bartlett Learning.

amount of oxygen supplied to the tissues is inadequate. Diseases that can lead to respiratory emergencies include asthma, emphysema, and chronic bronchitis. Cardiovascular emergencies are caused by conditions affecting the circulatory system. The most common examples that require EMS intervention include myocardial infarction and heart failure. Neurologic emergencies involve the brain and may be caused by a seizure, stroke, or fainting (syncope). Many gastrointestinal conditions are true emergencies and can result in a call to EMS for help. The most well-known of these gastrointestinal emergencies is appendicitis, although there are many others, including diverticulitis and pancreatitis. A urologic emergency can involve kidney stones. The most common endocrine emergencies are caused by complications of diabetes mellitus. Hematologic (blood-related) emergencies may be the result of sickle cell disease or various types of blood clotting disorders such as hemophilia. Immunologic emergencies involve the body's response to foreign substances. When the body overreacts to a foreign substance, the condition is commonly referred to as an allergic reaction. Allergic reactions are a type of immunologic medical emergency that can range from fairly minor conditions to life-threatening anaphylaxis. Toxicologic emergencies, including poisoning and substance abuse, result in other types of medical emergencies. Some medical emergencies are caused by psychological or behavioral problems. Behavioral emergencies may be especially difficult to manage because patients often do not present with typical signs and symptoms. Some conditions, such as gynecologic conditions, will most likely be challenging for you

because there is little that you can do to treat patients with these conditions in the prehospital setting. The chapters in this section discuss each of these medical emergencies.

Patient Assessment

Assessment of a medical patient is similar to the assessment of a trauma patient but with a different focus. Whereas trauma assessments focus on the mechanism of injury or physical injuries, most of which are visible through a physical examination, medical patient assessment focuses on the **nature of illness (NOI)**, symptoms, and the patient's chief complaint. Information received from dispatch can be helpful in anticipating what you might find when you arrive on scene, but it is conceivable that what appears to be a traumatic emergency may in fact be a medical emergency or vice versa. For example, a patient may have a medical condition that resulted in a motor vehicle crash, or the patient may have sustained a large laceration and you fail to recognize that the patient has experienced a hypoglycemic event. Tunnel vision occurs when you become focused on one aspect of the patient's condition and exclude all others, which may cause you to miss an important injury or illness.

The major components of patient assessment include the following:

- Scene size-up
- Primary survey
- History taking
- Secondary assessment
- Reassessment

YOU are the Provider

Part 1

At 1422 hours, your ambulance is dispatched for a call involving a 47-year-old woman with back pain and difficulty urinating. You and your partner proceed to the scene, with a response time of about 6 minutes. On arrival, you are met by the patient's husband, who directs you to the patient. She is lying on the bed in the fetal position. A quick glance around the room reveals no visible hazards to you or your partner. The patient states that she has sharp pain in her right side toward the back, which increases in intensity when she tries to urinate. She further states that she has had this pain for 3 days and has not been eating or drinking as much as normal.

1. Which systems of the body may be causing the patient's signs and symptoms?
2. Does this patient require immediate transport?

See Chapter 10, *Patient Assessment*, for more on the assessment process.

Scene Size-up

You must complete a scene size-up. The most important aspect of this step is to make sure the scene is safe. Although hazards are not as obvious with medical emergencies as with trauma situations, they still exist and must be considered. For example, patients who are substance abusers may need help in potentially dangerous locations, and some patients may have guard dogs or weapons that could pose a threat to you.

It is also important that you follow standard precautions when you respond to an emergency, including wearing gloves and other protective equipment. After determining the number of patients who need assistance and considering whether you need additional help, your next task is to determine the NOI. What signs and symptoms is the patient experiencing? Evaluation of the NOI for a medical patient will provide you with an index of suspicion for different types of serious or life-threatening underlying illnesses. The **index of suspicion** is your awareness and concern for potentially serious underlying and unseen injuries or illness.

Words of Wisdom

Use the patient's chief complaint to guide your assessment, but do not get tunnel vision. A patient initially reporting dyspnea may present with difficulty breathing; crackles (formerly called rales); and coughing up pink, frothy sputum. Although the chief complaint may be shortness of breath, the underlying problem in such a case is heart failure. An inability to recognize the patient's actual condition may result in a delay in providing definitive treatment or providing inappropriate care.

Primary Survey

As you approach a medical patient, you should form a general impression of the person's condition. Do not let a relatively normal impression lull you into complacency; the conditions of many medical patients may not appear serious at first. Quickly

determine the patient's level of consciousness using the AVPU (*Alert*—is awake, follows commands, visually tracks people or objects—and oriented to person, place, and time; responsive to *Verbal* stimuli; responsive to *Pain*; *Unresponsive*) scale.

Identify life threats by quickly assessing the patient's Airway, Breathing, Circulation, Disability, and Exposure (ABCDEs). In responsive patients, ensure the airway is open and breathing is adequate. Consider applying oxygen at this time if there is any indication that breathing has been affected. For unresponsive patients, make sure to open the airway using the proper technique for their condition and take several seconds to evaluate their breathing. Apply oxygen to patients in shock, with difficulty breathing, and when low oxygen saturations are measured (SpO₂ less than 94%). Unresponsive patients may need airway adjuncts and ventilatory assistance with a bag-mask device. Quickly assess the circulation by checking the radial pulse in a responsive patient and the carotid pulse in the unresponsive patient, and by observing the patient's skin color, temperature, and condition (**FIGURE 16-1**).

Also quickly glance around the patient to identify any life threats such as severe bleeding or injury to the chest that affects the breathing. If any life threats are found, address them immediately.

Once you have completed the primary survey, you should have enough information to make a preliminary transport decision. The following patients should be considered in serious condition

FIGURE 16-1 Skin color can provide an early and fast indication of several disease processes. Cyanosis presents as blue skin or mucous membranes.

© SPL/Science Source.

and in need of rapid transport: patients who are unresponsive or who have an altered mental status, patients with airway or breathing problems, and patients with obvious circulation problems such as severe bleeding or signs of shock.

Words of Wisdom

A **sign** is something you can see or measure (a laceration or the patient's blood pressure). A **symptom** is what the patient tells you ("My head hurts").

History Taking

With a medical patient, history taking may be the only way to determine what the problem is or what may be causing the problem (**FIGURE 16-2**). This information may include both a history of present illness (why the patient called EMS today) and a medical history (previously experienced conditions that may or may not be influencing the present illness). Investigate the NOI by asking questions about the chief complaint—for example, about signs and symptoms associated with the chief complaint and the history of the present illness. Obtain a SAMPLE (Signs and symptoms, Allergies, Medications,

FIGURE 16-2 History taking is an important part of the assessment process.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history, and ask questions about the history of the present illness using the OPQRST-I (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, and Interventions) mnemonic. Follow up with questions such as, "Has anything like this ever happened before?" and if the patient answers yes, then ask, "What was done at that time?" and "How does this episode compare with previous episodes?"

YOU are the Provider

Part 2

The patient says that her symptoms began spontaneously 3 days ago. Urination is painful, but even when she is not urinating, she is still in pain. The pain is described as stabbing in the right flank area that seems to radiate to her groin. In tears, the patient says this is the worst pain she has ever felt in her life. She rates the severity a 10 out of 10. She tells you that she has no known allergies and takes no medications. Her medical history includes kidney stones approximately 13 years ago, but she does not remember them hurting this much.

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Nonlabored
Circulation	Strong, rapid radial pulses; skin warm and dry

- What are some other pertinent questions that you may want to ask the patient?
- On the basis of the patient's presentation, what do you suspect is the most likely cause of her discomfort?

Record any allergies, medical conditions, and medications that the patient takes. If the patient has a current list of medications, bring that along; if not, it may be necessary to collect the medications and take them to the hospital with the patient. Inquire about any over-the-counter medications and any herbal remedies the patient may have taken. Ask patients who are taking medications whether they are compliant with their drug regimen; that is, whether they are taking their medications in the dosages and at the times prescribed.

While you are obtaining the history from the patient, look around the scene for evidence that may also help you determine the history of the patient—for example, evidence of medication containers or medical devices that the patient may have been using. Look for medical alert tags, which can offer a wealth of information.

If the patient is unresponsive, try to obtain as much of the patient's medical history as possible from family members, friends, or bystanders, or from the scene itself. (If the advanced emergency medical technician [AEMT] does not obtain and document this information, it may be lost forever.) Family members or friends may know the patient's allergies, medications, or medical conditions. Ask whether the patient was complaining of any symptoms before becoming unresponsive.

Secondary Assessment

The secondary assessment is designed to identify any signs or symptoms of illness or injury that were not found during the primary survey. If the patient is critically ill or injured or the transport time is short, you may not have time to conduct a secondary assessment. In other cases, the secondary assessment may occur on scene or en route to the emergency department (ED).

Unresponsive patients are unable to tell you what is wrong, so you should always perform a full-body exam of these individuals. In contrast, responsive medical patients may not need a full-body exam, but you should perform a limited or focused assessment based on their chief complaint. For example, if you suspect a neurologic problem, you should check for a pulse and for motion and sensation in all of the patient's extremities; also check the patient's pupillary reactions.

Obtain a baseline set of vital signs. Often your partner can begin this process while you are asking about the medical history. Consider using the automatic blood pressure cuff for future assessments at regular intervals after first obtaining a manual reading. Depending on your local protocol, other important information to consider obtaining includes a blood glucose level and a pulse oximetry reading. End-tidal carbon dioxide monitoring should be considered if the patient complains of respiratory problems or if you suspect a stroke. Additionally, any patient who has a cardiac-related symptom should be placed on a cardiac monitor. Consider calling for paramedic backup if this is the case. The cardiac monitor enables the AEMT or the paramedic to monitor and record 3-lead electrocardiogram (ECG) tracings, and record 12-lead ECGs in the field. It also enables the provider to quickly identify a suspected acute myocardial infarction, transmit the findings electronically to the receiving facility, and make sound transport decisions regarding patient destination based on the ECG findings.

Reassessment

Once the assessment and treatment have been completed, reassessment should begin and continue throughout transport. During the reassessment, you should repeat the primary survey and reassess the chief complaint. Look for any changes in the level of consciousness, reassess the patient's vital signs, and reexamine the transport decision. Reconsider the need for paramedic backup. The reassessment also includes reviewing all treatments that have been performed and ensuring they are still effective. Document any changes that have developed as a result of the treatments and, if needed, adjust any of the treatments accordingly. Alert the ED before the arrival of potentially critical patients.

Management: Transport and Destination

Most medical emergencies require a level of treatment beyond that available in the prehospital setting. Also, the treatments depend on an accurate diagnosis of the exact medical condition, which may require advanced testing in a hospital. The primary prehospital treatments for medical emergencies

address the symptoms more than the actual disease process.

The ability to administer medications that are stored in the ambulance is limited for AEMTs and depends on the scope of practice, along with state and local protocols. A few of these protocols include administering oral glucose or glucagon to a patient with diabetes and a low blood glucose level, administering naloxone to a patient with a narcotic overdose, and administering albuterol to a patient with respiratory difficulty. The administration of activated charcoal to a patient who has ingested a poison is also allowed when it may be beneficial.

Each of these situations and any other administration of medications by an AEMT require that direct permission be obtained from medical control. Written protocols may allow the administration of certain medications without calling for online medical control, so it is important to be familiar with the guidelines for your EMS agency. The process of obtaining permission includes completing a thorough assessment of the patient before calling medical control. After you give a report to the physician and obtain permission, the medication may be administered. Never administer any medication without first obtaining permission from medical control (either online or off-line), and always follow your state and local protocols.

You may also use an automated external defibrillator (AED) on a patient who is pulseless and apneic. In some cases of cardiac arrest, immediate treatment with an AED may provide the best option to resuscitate the patient. Familiarize yourself with the equipment and medications carried on your ambulance and use them appropriately under a medical director's instruction. The AED is discussed in more detail in Chapter 18, *Cardiovascular Emergencies*.

Scene Time

In many cases, the time on scene may be longer for medical patients than for trauma patients. If the patient is not in critical condition, gather as much information as possible from the scene so that you can transmit that information to the physician at the ED. Critical patients include those with altered mental status, airway or breathing difficulties, or any sign of circulatory compromise. In addition, a patient who is very old or very young may be

considered critical even if they appear to be relatively stable. Critical patients always need rapid transport. The time on scene should be limited to 10 minutes or less for these patients.

Type of Transport

Serious consideration should be given to how to best transport a medical patient. If a life-threatening condition exists, the transportation should include lights and siren, but if the patient is not critical, consider nonemergency transport. Many patients experiencing a medical emergency do not have immediate life-threatening conditions; therefore, they can be transported without the use of lights and siren. This is a much safer method of transport and will often result in arrival only a few minutes later than an emergency transport using lights and siren.

Differentiating a high-priority transport from a low-priority transport is a skill developed with experience, but it is a skill that can be learned. A good rule of thumb for determining the priority of transport is to consider the results of the patient's primary survey. Patients with an altered mental status, especially if it is still present at the completion of your assessment and treatment, should be considered a high-priority transport. Patients with circulatory compromise, including signs and symptoms of shock, should also be considered a high-priority transport. Most patients with circulatory conditions cannot be stabilized in the prehospital setting and need to receive treatment at a hospital quickly but safely. Patients with difficulty breathing generally require high-priority transport. However, if the patient has responded well to your initial treatment, such as oxygen and albuterol administration, lights and siren may not be necessary.

Words of Wisdom

When transporting a patient who has had a seizure, do not use lights and siren unless the patient is in status epilepticus and actively seizing. The additional stimulus may precipitate a new onset of seizures.

Modes of transport ultimately come in one of two categories: ground (**FIGURE 16-3**) or air (**FIGURE 16-4**). Ground transportation EMS units are generally staffed by emergency medical technicians

FIGURE 16-3 Ground transport.

FIGURE 16-4 Air transport.

© LindaCharlton/iStock/Getty Images.

(EMTs) and advanced life support providers (AEMTs or paramedics). Air transportation EMS units or critical care transport units are generally staffed by critical care transport professionals such as critical care nurses and paramedics. Although it is not as common to summon an air ambulance for a medical patient, there are instances where it is advisable. In rural areas with long ground transport times, patients who have possibly experienced a heart attack, a stroke, or a complication of pregnancy could benefit from air transport to the most appropriate facility. Children with serious medical conditions can also benefit from air transport. When you are considering additional paramedic support for a patient, compare the total time for a ground unit to respond and transport to the time required for a helicopter to respond and transport as well as the urgent resources needed by the patient. Follow local protocols and medical direction.

For more information on air ambulances, see Chapter 39, *Transport Operations*.

Destination Selection

It is generally appropriate to select the closest ED as your destination. However, there are times when the closest hospital is not necessarily the most appropriate choice. Patients with chest pain as the result

YOU are the Provider

Part 3

After explaining to the patient that you believe she is experiencing her pain as the result of a new kidney stone, you obtain consent for treatment and transport and assist her to the stretcher. As you are securing her, she requests to be placed on her left side because it helps to slightly reduce the pain.

Recording Time: 6 Minutes

Respirations	22 breaths/min, normal
Pulse	Strong and rapid, 114 beats/min
Skin	Warm and dry
Blood pressure	164/92 mm Hg
Oxygen saturation (SpO₂)	100% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Does this patient require an intravenous (IV) line?
- Does this patient require treatment at a specific hospital, or should you transport her to the closest community hospital?

of a myocardial infarction may need a facility that is capable of performing heart catheterization, which may not necessarily be available at the closest hospital. If the patient is in cardiac arrest or experiences cardiac arrest during transport, immediately reroute to the closest hospital with emergency facilities. Patients with stroke can also benefit from specialized hospital selection. Although most hospitals now have designated stroke teams, taking a patient with a possible stroke to a hospital without a stroke team may result in a delay in definitive treatment and may lead to a worse outcome for the patient. Your local protocols should provide guidance on the appropriate facility, but contact medical control when unsure.

Some medical patients may benefit from on-scene treatment provided by paramedics. It is important to recognize early when paramedics can provide added value on a scene so that, if they are readily available, they can be called to respond in a timely manner or intercept the transport en route to the hospital.

Infectious Diseases

You will be called on to treat and transport patients with a variety of infectious or communicable diseases. Therefore, you must understand the routes of transmission and standard precautions that responders need to take to reduce risk and increase prevention. This chapter discusses the management, awareness, and assessment of a patient who may have a communicable or infectious disease. Chapter 2, *Workforce Safety and Wellness*, discusses communicable diseases and methods to prevent their transmission, and Chapter 39, *Transport Operations*, discusses decontamination techniques for transport.

Words of Wisdom

An *infectious* disease is a medical condition caused by the growth and spread of harmful organisms within the body. A *communicable* disease is a disease that can be spread from one person or species to another. Most of these diseases are much harder to transmit than is commonly believed. In addition, there are many immunizations, protective techniques, and devices that can be used to minimize your risk of infection. When these protective measures are used, the risk of your contracting a serious infectious disease is reduced.

General Assessment Principles

The assessment of a patient suspected to have an infectious disease should be approached much like any other medical patient. First, the scene must be sized up and standard precautions taken with consideration for the potential infectious agent. Once you can be assured that the scene is safe, proceed with the primary survey by assessing the patient's ABCDEs. Prioritize the treatment of the patient. With most patients who have a potentially infectious disease in the prehospital setting, the next step is to gather patient history, using OPQRST-I to elaborate on the patient's chief complaint. Typical chief complaints include fever, nausea, rash, pleuritic chest pain (a sharp, stabbing, or burning chest pain that fluctuates, usually increasing on inhalation and becoming worse with deep breathing, coughing, sneezing, or laughing), and difficulty breathing. Obtain a SAMPLE history and a set of baseline vital signs, paying particular attention to medications the patient is currently taking and the events leading up to today's problem. Also ask whether the patient has recently traveled. Always show respect for the feelings of the patient, family members, and others at the scene.

General Management Principles

The general management of the patient with a suspected infectious disease first focuses on any life-threatening conditions that were identified in the primary survey (airway maintenance, oxygen and ventilatory assistance, bleeding control, and circulatory support). Remember to be empathetic. Because most of these patients will have a fever of unexplained origin or mild breathing problems, place the patient in the position of comfort on the stretcher to keep warm. Remember to use standard precautions for your own

Words of Wisdom

The ability of your EMS service to support you in the event of exposure to a communicable disease depends on your understanding of how an exposure can occur and your immediate reporting of exposure to potentially infectious materials. Make notes right away to ensure that you remember all pertinent information, and report the possible exposure immediately after the response, following your local protocol.

safety. Always follow your agency's exposure control plan in cleaning equipment, and properly discard any disposable supplies as well as linens.

Epidemic and Pandemic Considerations

An **epidemic** occurs when new cases of a disease in a human population substantially exceed the number expected based on recent experience. A **pandemic** is an outbreak that occurs on a global scale or over a wide area. For example, a flu pandemic occurs when a new influenza virus for which people have little or no immunity emerges. The disease can then spread easily from person to person, cause serious illness, and be found in multiple countries in a short time. Obviously, there would be no specific vaccine immediately available.

Words of Wisdom

The term herd immunity became prevalent during the COVID-19 pandemic. Herd immunity refers to protection of the greater population from a disease when enough of the population becomes immunized to it, either through vaccines or from previous infection and recovery from the disease. It is an important goal in ending an infectious disease outbreak.

Common or Serious Communicable Diseases

Human Immunodeficiency Virus Infection

Human immunodeficiency virus (HIV) type 1 was identified in the United States in the 1980s. According to the US Centers for Disease Control and Prevention (CDC), more than 1.2 million people in the United States are infected with this virus and 1 in 7 do not know they are infected.¹ The annual number of new HIV diagnoses has continued to decline since 2005, which may be attributed to targeted prevention efforts; however, gay and bisexual men, particularly young African American gay and bisexual men, represent a disproportionate share of new diagnoses.¹

HIV infection is a potential hazard only when deposited on a mucous membrane or directly into the bloodstream. It is primarily a sexually transmitted disease, but it is also a bloodborne disease. It can also be transmitted from a pregnant woman to her infant in the birthing process. HIV is also transmitted through blood transfusions, although such transmission is not common because donated blood is now tested for a protein indicating the presence of HIV.

In a person infected with HIV, the entire immune system begins to fail, allowing life-threatening opportunistic infections to flourish. The HIV pathogen envelops infected cells and attacks the immune system

Words of Wisdom

Causes of Infectious Disease

Type of Organism	Description	Example
Bacteria	Grow and reproduce outside the human cell in the appropriate temperature and with the appropriate nutrients	<i>Salmonella</i>
Viruses	Smaller than bacteria; multiply only inside a host and die when exposed to the environment	Human immunodeficiency virus
Fungi	Similar to bacteria in that they require the appropriate nutrients and organic material to grow	Mold
Protozoa (parasites)	Single-celled microscopic organisms, some of which cause disease	Amoebas
Helminths (parasites)	Invertebrates with long, flexible, rounded, or flattened bodies	Worms

and other body organs. The immune system is then unable to assist in protecting the infected person from other diseases. It takes approximately 7 days for the virus to envelop a cell, and this process may occur 4 to 6 weeks after the exposure event. The communicable period is unknown, but is believed to span from the onset of infection possibly throughout life.

Many patients who are infected with HIV do not show any symptoms. For those who are symptomatic, signs and symptoms may include acute febrile illness, malaise, fatigue, sore throat, swollen spleen and lymph glands, headache, weight loss, and possibly rash. Following initial infection, most patients present with enlargement of the lymph nodes and appear healthy. However, the immune system ultimately becomes weakened.

Acquired immunodeficiency syndrome (AIDS) is the end-stage disease process caused by HIV infection. A patient with AIDS is extremely vulnerable to numerous bacterial, viral, and fungal infections that would be easily brushed aside in a person with an intact immune system. These opportunistic infections include pneumonia in infants or people with compromised immune systems, loss of vision due to cytomegalovirus, red/purple skin lesions, atypical tuberculosis, and cryptococcal meningitis.

The incubation period of AIDS spans the time between documented infection (ie, becoming HIV positive) and development of the end-stage disease. The communicable period for HIV infection begins before clinically apparent AIDS develops.

Prehospital management of HIV/AIDS is supportive. Support the airway and respiratory status, assisting ventilations as needed. Establish IV access and give a fluid bolus of an isotonic crystalloid solution if the patient is hypovolemic. Use a nonrebreathing mask or other mask for respiratory isolation if the patient is coughing.

Exposure to HIV is a risk that AEMTs face on a regular basis. It is this prospect that led to the development of standard precautions. There is no vaccine to protect against HIV infection, and despite great progress in drug treatments, AIDS can still be fatal. Fortunately, HIV is not easily transmitted in your work setting. For example, it is far less contagious than hepatitis B. Because HIV infection can only occur via sexual contact or exposure to blood or body fluids, your risk of infection is limited to exposure to an infected patient's blood and body fluids. Exposure can take place in the following ways:

- The patient's blood is splashed or sprayed into your eyes, nose, or mouth or into an open sore or cut, however tiny; even a microscopic opening in the skin is an invitation for infection with a virus. The risk of HIV transmission after exposure of the eye, nose, or mouth to HIV-infected blood is estimated at only 1 in 1,000; the risk after cut exposure is approximately 1 in 300.²
- You have blood from the infected patient on your hands and then touch your own eyes, nose, mouth, or an open sore or cut.
- A needle used to inject the patient breaks your skin. The risk to you from a single injection, even with a hollow-bore needle, is small, probably less than 1 in 300.² However, this is by far the most dangerous form of exposure for EMS providers.
- Broken glass at a motor vehicle crash or other incident penetrates your glove (and skin), which may have already been covered with blood from an infected patient.

Because many patients who are infected with HIV do not show any symptoms, health care workers should wear gloves any time they are likely to come in contact with secretions or blood from any patient. Always put on gloves before leaving the ambulance to care for a patient. Also, take great care in handling and properly disposing of needles and other sharp objects in a sharps container so that you and others are not inadvertently exposed to them. Finally, cover any open wounds that you have whenever you are on the job.

If you have any reason to think that a patient's blood or secretions may have entered your system, especially through contact with a patient's blood, seek medical advice as soon as possible and notify your infectious disease officer. If you know that the patient is infected with HIV, current recommendations from the CDC include immediate prophylactic treatment as soon as possible after exposure to prevent you from becoming infected. Treatment should continue for a 4-week duration and expert consultation should be sought. If testing proves negative, treatment may be discontinued.³

Safety

An AEMT with a cold or the flu can be extremely hazardous to a patient who is immunocompromised.

As scientists learn more about HIV infection, testing and treatment recommendations change. It is important that you immediately see your physician (or your program's designated physician) anytime you have a significant exposure to a communicable or infectious disease. Know the policy for your system and take time now to consider what you would do in the event of exposure.

Influenza

Influenza, commonly known as flu, can affect all people, but those with chronic medical conditions, compromised immune systems, the very young, and the very old are particularly susceptible to complications of the disease. All strains of influenza are transmitted by direct contact with nasal secretions and aerosolized droplets from coughing and sneezing by infected people.

The H1N1 virus, a strain of which caused the swine flu pandemic in 2009, is a specific form of influenza.⁴ This virus has been present for years in animals. Many deaths have been caused by the H1N1 virus, although deaths caused by other influenza viruses have also occurred. The most positive effect of the outbreak of the H1N1 virus has been the general public's greater awareness of the routes of transmission of contagious diseases. This increased awareness could result in a reduction of all communicable diseases, not only H1N1.

General treatment for a patient with influenza includes supportive treatment. Place the patient in a position of comfort and be alert for potential vomiting. Oxygen is generally not needed for patients with influenza, but potential comorbid conditions may warrant the application. Gain IV access and consider the administration of a 20-mL/kg bolus of an isotonic crystalloid solution. Patients with influenza may quickly dehydrate from vomiting or lack of fluid intake. Keep the patient warm during transport.

In addition to influenza, many potentially serious diseases can be passed by the respiratory route; therefore, you need to wear personal protective equipment (PPE), such as gloves, eye protection, and a high-efficiency particulate air (HEPA) respirator, at a minimum. Viruses can live for several days on surfaces, so frequent handwashing is also important. Maintain your vaccinations and stay up-to-date on the latest CDC recommendations. Place a surgical mask on patients with suspected or confirmed respiratory disease. Wear a

HEPA respirator during any aerosol-generating procedures such as suctioning of airway secretions, performing cardiopulmonary resuscitation, or assisting with endotracheal intubation.

An annual influenza immunization is important, especially for EMS personnel, to protect both providers and patients. The influenza virus is constantly changing. Experts adjust vaccines from year to year to provide protection against the strains most likely to affect the population. Vaccination effectively decreases transmission rates and limits (though does not eliminate) the disease incidence. Complications of the vaccine are far less common and severe than complications of the flu. The theory that immunizations cause autism has been proven through research to be untrue. Remember, people die each year from influenza virus, which is often transmitted by people who have failed to be immunized. Health care workers should not become the source of such transmission. Make sure you are immunized annually, and if you are sick, do not come to work and expose your patients to a disease that could prove fatal to them.

Hepatitis

The term **hepatitis** refers to an inflammation (and often infection) of the liver. Hepatitis can be caused by many different viruses and toxins. Complications of hepatitis include scarring of the liver, liver cancer, and liver failure. According to the CDC, of the three types of viral hepatitis (designated as A, B, and C), hepatitis C accounted for the greatest number of deaths and the highest mortality rate in the United States.⁵

Depending on the severity of the infection, patients with hepatitis may be asymptomatic or may have a variety of signs and symptoms. Early signs of viral hepatitis include loss of appetite, vomiting, fever, fatigue, sore throat, cough, and muscle and joint pain. Several weeks later, jaundice (yellow eyes and skin) and right upper quadrant abdominal pain develop (**FIGURE 16-5**). Acute liver failure, also known as fulminant hepatitis, is a rare but potentially fatal disease that may occur after infection with viral hepatitis. The severity of toxin-induced hepatitis depends on the amount of agent absorbed and the duration of exposure. Toxin-induced hepatitis is not contagious.

Management of patients with any type of hepatitis is strictly supportive. Maintain a patent airway,

FIGURE 16-5 Jaundice is a sign of a hepatitis infection.

© SPL/Science Source.

give 100% oxygen, and assist ventilations as needed. Establish IV access, and if fluid resuscitation is needed, give a 20-mL/kg bolus of an isotonic crystalloid solution. If no trauma is suspected, transport in a position of comfort to the closest, most appropriate facility.

There is no sure way to tell which patients with hepatitis have a contagious form of the disease and which do not. **TABLE 16-2** lists the characteristics of different types of hepatitis, from which you can assess your risk of exposure. Hepatitis A can be transmitted only from a patient who has an acute infection, whereas hepatitis B and hepatitis C can be transmitted from long-term carriers who have no signs of illness. A carrier is a person (or animal) in

TABLE 16-2 Characteristics of Hepatitis					
Type	Route of Infection	Incubation Period	Chronic Infection	Vaccine and Treatment	Comments
Viral Hepatitis					
Hepatitis A (infectious)	Fecal–oral, infected food or drink	2–6 weeks	Chronic condition does not exist	Vaccine is available; no specific treatment is available; body will clear the infection on its own	Mild illness; mortality is approximately 0.02 patients per 100,000 population; after acute infection, the patient has life-long immunity
Hepatitis B	Blood, sexual contact, saliva, urine, breast milk	4–12 weeks	Chronic infection affects 2% to 6% of adult patients and up to 90% of newborns who have the disease	Vaccine is available; treatment is minimally effective	Chronic carriers are asymptomatic and without signs of liver disease, but they may infect others; mortality is approximately 0.5 deaths per 100,000 population
Hepatitis C	Blood, sexual contact	2–10 weeks	Chronic infection affects 75% to 85% of patients	No vaccine is available; treatment is costly but effective for many strains of hepatitis C	Cirrhosis of the liver develops in 5% to 20% of patients with hepatitis C; chronic infection increases the risk of cancer of the liver; mortality is approximately 5.0 deaths per 100,000 population

Type	Route of Infection	Incubation Period	Chronic Infection	Vaccine and Treatment	Comments
Hepatitis D	Blood, sexual contact	4–12 weeks	Chronic infection develops in only 5% of patients with acute infection	No vaccine is available; no treatment is available	Occurs only in patients with active hepatitis B infection; superinfection of hepatitis D in the presence of chronic hepatitis B leads to more severe disease in 70% to 90% of cases
Hepatitis E (epidemic non-A, non-B hepatitis)	Fecal–oral, contaminated water or food	15–60 days	Usually resolves on its own over several weeks to months	No vaccine is available; no treatment is available	Mild illness; fatal in approximately 1% of all cases; fulminant disease may develop, especially in pregnant patients; mortality is as high as 20% to 25% in pregnant women in the third trimester who develop fulminant hepatitis E
Hepatitis G (hepatitis GB)	Blood, sexual contact, breast milk	Possibly 15–50 days	Mild and usually short-lived	No vaccine is available; no treatment is available	Can cause severe liver damage resulting in liver failure; often seen in conjunction with hepatitis B, hepatitis C, or both
Toxin-Induced Hepatitis					
Medications, drugs, and alcohol	Inhalation, skin or mucous membrane exposure, oral ingestion, or intravenous administration	Within hours to days following exposure	Some chemicals may initiate an inflammatory response that continues to cause liver damage long after the chemical is out of the body	No vaccine is available; treatment is to stop exposure; in patients with an overdose of acetaminophen, certain drugs may minimize liver injury if given early enough	Not contagious; patients with toxin-induced hepatitis may have liver damage and jaundice; not every exposure to a toxin will cause liver damage

whom an infectious organism has taken up permanent residence and may or may not cause any active disease. Carriers may never know that they harbor the organism; however, they can infect other people.

Hepatitis A is transmitted orally through oral or fecal contamination. This means that, generally, you must eat or drink something that is contaminated with the virus. The organisms that cause hepatitis B, C, and G are transmitted through vehicles other than food or water. For example, these organisms may enter the body through a transfusion or needlestick with infected blood, which puts health care workers at high risk for contracting hepatitis B, the more contagious and virulent form. **Virulence** is the strength or ability of a pathogen to produce disease. Hepatitis B is far more contagious than HIV. For this reason, vaccination with hepatitis B vaccine is highly recommended for AEMTs. Unfortunately, immediate immunity to the virus does not develop in everyone who is vaccinated. Sometimes, but not always, an additional dose will provide immunity. You should be tested after vaccination to determine your immune status.

If you are stuck with a needle or injured in some other way while caring for a patient who might have hepatitis, see your physician immediately.

Herpes Simplex

Herpes simplex is a common virus strain carried by humans. Most people carrying the virus are asymptomatic. Symptomatic infections cause eruptions of tiny fluid-filled blisters called vesicles that often appear on the lips or genitals. Herpes simplex can also cause more serious illnesses like pneumonia and meningitis in the very young, very old, and immunocompromised patients. The primary mode of infection is through close personal contact, so standard precautions are generally sufficient to prevent spread to or from health care workers.

Syphilis

Although syphilis is commonly thought of as a sexually transmitted disease, it is also a bloodborne disease. There is a small risk for transmission through a contaminated needlestick injury or direct blood-to-blood contact.

The initial infection with syphilis produces a lesion called a chancre. Chancres are most commonly located in the genital region. For more

information on syphilis, see Chapter 25, *Gynecologic Emergencies*.

Meningitis

Meningitis is an inflammation of the meningeal coverings of the brain and spinal cord. Patients with meningitis develop signs and symptoms such as fever, headache, stiff neck, and altered mental status. This uncommon but very frightening infectious disease can be caused by viruses or bacteria, most of which are not contagious. However, one form, **meningococcal meningitis**, is highly contagious. The meningococcal bacterium colonizes the human nose and throat and only rarely causes an acute infection. When it does, it can be lethal. Patients with this kind of infection often have red blotches on their skin, fever, and nuchal rigidity; however, many patients with forms of meningitis that are not contagious also have red blotches.

Only laboratory tests can sort out the different forms of meningitis; therefore, you should take standard precautions with any patient who is suspected of having meningitis. Wearing gloves and a mask will go a long way toward preventing the patient's secretions from entering your nose and mouth. Be aware that the risk of infection is low, even if the organism is transmitted. Vaccines are available for most types of meningococcus. Although the recommendation has rarely been followed, the CDC recommends that all 11 to 12 year olds receive a meningococcal conjugate vaccine, with a booster dose at age 16 years. Meningitis can be treated at the ED with antibiotics.

After treating a patient with meningitis, contact your employer health representative. Many states consider meningitis "reportable" and will notify you that one of your patients was diagnosed with meningitis. Prophylactic treatment may be recommended for you.

Tuberculosis

Most patients who are infected with *Mycobacterium tuberculosis* (the tubercle bacillus) are well most of the time. If the disease involves the brain or kidneys, the patient is only slightly contagious. In the United States, however, **tuberculosis** is a chronic mycobacterial disease that usually strikes the lungs. Disease that occurs shortly after infection is called primary tuberculosis. Except in infants, this infection is not usually serious. After the primary

infection, the tubercle bacillus is rendered dormant by the patient's immune system. However, even after decades of lying dormant, this germ can reactivate. Reactive tuberculosis is common and can be much more difficult to treat, especially because an increasing number of tuberculosis strains have grown resistant to most antibiotics.

Safety

Place a surgical mask on any patient suspected of having tuberculosis and a HEPA mask on yourself.

Although tuberculosis is often difficult to distinguish from other diseases, patients who pose the highest risk almost invariably have a cough. Therefore, for your own safety, you should consider respiratory tuberculosis to be the only contagious form because it is the only one that is spread by airborne transmission. The droplets produced by coughing are not the real problem, but rather the droplet nuclei—that is, the remnants of the droplets after the excess water has evaporated. These particles are tiny enough to be invisible and can remain suspended in the air for a long time. As long as these particles are shielded from ultraviolet light, they can remain alive for decades. Particles that are the size of droplet nuclei are not stopped by routine surgical masks. When inhaled, they are carried directly to the alveoli of the lungs, where the bacteria may begin to grow. N95 or HEPA masks are required to prevent the inhalation of droplet nuclei. For a patient with dyspnea, wearing a nonrebreathing mask has two benefits: it oxygenates the patient while providing a barrier to prevent the droplets from spreading to the AEMT. If the patient is not having difficulty breathing, place a surgical mask on the patient and a HEPA mask on yourself.

Why is tuberculosis not more common than it is? After all, absolute protection from infection with the tubercle bacillus does not exist: everyone who breathes is at risk. According to the WHO, one-fourth of the world's population is infected with tuberculosis.⁶ The vaccine for tuberculosis, called bacillus Calmette-Guérin, is rarely used in the United States because of the low risk of infection.⁷ It is recommended only in specific situations. Under normal circumstances, the mechanism of transmission used by *M tuberculosis* is not very efficient.

Infected air is easily diluted with uninfected air. *M tuberculosis* is one of those germs that typically cause no illness in a new host. In fact, many patients with tuberculosis do not even transmit the infection to family members. However, in crowded environments with poor ventilation, the disease spreads more easily.

If you are exposed to a patient who is found to have pulmonary tuberculosis, you will be given a tuberculin skin test. This simple skin test determines whether a person has been infected with *M tuberculosis*. A positive result means that exposure has occurred; it does not mean that the person has active tuberculosis. It takes at least 6 weeks for the bacteria to show up in the laboratory test. So, if you are tested for the disease within a few weeks of the exposure and your results are positive, this outcome means that you were exposed to tuberculosis at an earlier time from somebody else. You will probably never identify the source. Most transmissions occur silently, so it is necessary that you have tuberculin skin tests regularly. If the infection is found before you become ill, preventive therapy

Special Populations

Everyone has body defenses that help protect against illness, but the aging process can pose a threat to the body's natural defense mechanisms against invading microorganisms. As people age, their physical defenses weaken or are eliminated. Thinning and loss of supportive collagen in the skin and a reduction in the number of blood vessels, for example, can allow bacteria or viruses to enter the body with less resistance. The respiratory system cannot trap and eliminate bacteria and viruses in the airways as efficiently as it once did. Moreover, the gastrointestinal system allows easier entry for bacteria or viruses through the intestines. As the body ages, physical barriers to entry weaken, the immune system deteriorates, and invading organisms are not as easily identified as abnormal. Infectious agents can take hold in elderly patients much more easily because of reduced defenses.

When transporting an elderly patient, protect the patient from the environment because extremes in heat or cold can further reduce the body's defenses. If the patient has a cold or the flu, protect yourself. However, remember that your defense system is probably much stronger than that of the patient.

is almost 100% effective. Usually, a daily dose of the medication isoniazid will prevent the development of active infection.

Pertussis

Pertussis, also called whooping cough, is an airborne disease caused by bacteria that previously affected primarily children younger than 6 years, but is becoming more common in adults whose vaccination occurred years prior and whose immunity has decreased. Signs and symptoms include fever and a “whoop” sound that occurs when the patient tries to inhale after a coughing attack.

The best way to prevent infection from pertussis is to be vaccinated with a diphtheria, tetanus, and acellular pertussis (DTaP) vaccine. Providers who have previously received this vaccine should make sure they are up-to-date with a booster. For added protection, place a mask on the patient and on yourself.

Methicillin-Resistant *Staphylococcus aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a bacterium that causes infections and is resistant to many antibiotics. **Nosocomial** infections with MRSA are believed to be transmitted from patient to patient via the unwashed hands of health care providers. Studies have shown that 1% to 5% of health care providers carry MRSA in their nares.⁸ The pathogen can subsequently be transferred to the skin and to and other areas of the body through a break in the skin. Surfaces contaminated with MRSA do not seem to be important in transmission. Factors that increase the risk for developing MRSA include antibiotic therapy, prolonged hospital stays, a stay in an intensive care or burn unit, and exposure to an infected patient.

The incubation period for MRSA appears to be between 5 and 45 days. The communicable period varies, as patients who have active infection may carry MRSA for months. MRSA results in soft-tissue infections. Its signs and symptoms may involve localized skin abscesses, and sepsis may be found in older patients with the infection.

To prevent MRSA transmission, use standard precautions (gloves and good handwashing technique) when in contact with patient wounds and nonintact skin. If you are in direct contact with wound drainage but your skin is intact, no exposure

will occur. If you have a true exposure, no post-exposure treatment is recommended. The incident must still be documented, however.

New and Emerging Diseases

Newly recognized diseases, such as those caused by Hantavirus (a rare but deadly virus transmitted through rodent urine and droppings) and enteropathogenic *Escherichia coli* (a common cause of pediatric diarrhea in developing countries), are being reported. These diseases are not transmitted from person to person directly; rather, they are carried by a vehicle, such as food, or a vector, such as rodents.

West Nile Virus

Although not a newly discovered illness, West Nile virus has caused some concern in the past. The virus's vector, the mosquito, affects humans and birds. The virus is tracked by tests done on birds suspected of being killed by the virus. These diseases are not communicable and do not pose a risk to you during patient care.

Severe Acute Respiratory Syndrome

A virus that caused significant concern in the recent past is **severe acute respiratory syndrome (SARS)**. SARS is a serious, potentially life-threatening viral infection caused by a recently discovered family of viruses. SARS usually starts with flulike symptoms, which may progress to pneumonia, respiratory failure, and, in some cases, death. The SARS virus strain probably spread from Guangdong province in southern China to Hong Kong, Singapore, and Taiwan.⁹ Canada experienced a significant outbreak in the Toronto area in 2003.⁹ SARS is thought to be primarily transmitted by close person-to-person contact. Most cases have involved people who lived with or cared for a person with SARS or who had exposure to contaminated secretions from a patient with SARS. There have been no reported cases of SARS in recent years.

Avian Flu

Avian (bird) flu is caused by a virus (designated as H5N1) that occurs naturally in the bird population. This virus is carried in the intestinal tract of wild birds and does not usually cause illness. However, in domestic bird populations (eg, chickens, ducks,

and turkeys), it is very contagious. Birds acquire the illness from contact with contaminated excretions or surfaces that are contaminated with excretions. If an infected bird is used for food and is cooked, it does not pose a risk to those who eat it.

The first case of this flu was reported in Hong Kong in 1997; 18 people became infected and 6 died in the outbreak. Since then, the incidence has been decreasing, but H5N1 can still be fatal.¹⁰ No cases of rapid human-to-human transmission of this disease have been reported. Instead, the cases occurring in humans have involved close contact with infected birds. The transmission risk for humans is low.

Global Health Issues

Middle East Respiratory Syndrome Coronavirus

Middle East respiratory syndrome coronavirus (MERS-CoV) is a virus most commonly found in bats and camels living in the Middle East. The first human case of MERS-CoV was discovered in 2012 in Saudi Arabia. Although most clusters of human infections are found in the Middle East, cases of MERS-CoV have also been reported in Europe and the United States. Common patient symptoms include high fever, cough, muscle aches, vomiting, and diarrhea. In some cases, renal failure, respiratory failure, and death have been reported. There is presently no cure or vaccine for this virus. If you suspect your patient might have MERS-CoV, place a surgical mask on the person and notify the receiving facility.

Coronavirus Disease 2019 (COVID-19)

The first report of an emerging new respiratory illness in the city of Wuhan, China, occurred on December 31, 2019.¹¹ This viral illness caused severe respiratory symptoms, leading to respiratory failure and, in some cases, death. The disease spread rapidly, infecting family members of ill people and health care workers caring for them. Cases began occurring in people with no known contact with other ill people, indicating that the virus was spreading in the general population. The virus was soon identified as a novel (new) coronavirus and named severe acute respiratory syndrome coronavirus 2

(SARS-CoV-2) because it is a close cousin to the MERS-CoV and SARS virus. The disease it causes was called coronavirus disease 2019 (COVID-19).

Within 3 weeks of the initial report, cases of the new disease had been reported in Japan, Korea, Thailand, and the United States. On March 11, 2020, the World Health Organization characterized COVID-19 as a pandemic.¹² Despite applying lessons learned from previous pandemics and natural disasters, governments, public health systems, and health care delivery systems across the world were woefully unprepared for the COVID-19 pandemic.

Special Populations

Studies involving children hospitalized for coronavirus infection revealed that a small percentage developed a rare condition called multisystem inflammatory syndrome in children (MIS-C). The disorder causes inflammation of the heart, lungs, kidneys, eyes, and brain. Before COVID-19, the syndrome did not exist.

COVID-19 is a highly contagious respiratory infection that can cause a constellation of symptoms that emerge anywhere from 2 to 14 days after exposure. Fever, chills, cough, shortness of breath, body aches, headache, and a loss of taste and smell are key complaints. The virus may additionally attack the walls of the heart and the lining of blood vessels; cause blood clots, strokes, seizures, and brain inflammation; and injure the kidneys. Yet many people infected with the virus never develop COVID-19 symptoms. Even though this critical group does not get sick, it remains capable of transmitting the infection to others. These silent spreaders are the reason the CDC recommended that all people wear masks in public during the height of the pandemic.

Safety

A study by Greek scientists, published in the journal *Physics of Fluids*, argued that with a breeze of as little as 2.5 mph, it takes only 5 seconds for tiny aerosolized droplets to travel 18 feet.¹³ Standard social distancing of 6 feet may not offer needed protection from exposure.

Transmission of SARS-CoV-2 occurs primarily via respiratory droplets that an infectious person expels when talking (especially loudly), singing, coughing, or sneezing. The droplets may linger in the air for a short period and are unlikely to travel more than a few feet. Six feet has been the recommended distancing to avoid exposure from an infected person. However, weather and wind conditions may greatly affect this distance. Prolonged close proximity with an infected person, such as having a close conversation, causes transmission. Respiratory particles that contain the virus and land on surfaces can survive up to a day, and longer on some nonporous surfaces. Surfaces, therefore, are another means of

transmission, though less often because of the lower number of active viruses that survive on contaminated surfaces. Nevertheless, touching a surface that has the virus and then touching one's mouth, eyes, or nose can cause transmission. As with other pathogens, the chance of becoming sick increases with the amount of virus that enters one's body, so the longer the contact or larger the exposure, the higher the chance of infection.^{14,15}

People at highest risk of serious illness following infection are older adults and people with an underlying medical condition (TABLE 16-3). However, anyone, including healthy children and young adults, can become sick with COVID-19.

TABLE 16-3 People at Higher Risk for Severe Illness Following COVID-19 Infection

Older adults. Risk of severe illness or death following infection with the virus increases dramatically with each increase in age group. Compared to people ages 18 to 29 years: • Those 65 to 74 years old are 5 times more likely to become hospitalized and 73 times more likely to die. • Those 75 to 84 years old are 8 times more likely to be hospitalized and 186 times more likely to die. • Those older than 85 years are 11 times more likely to be hospitalized and 527 times more likely to die.
Comorbidity. Adults of any age with the following conditions <i>are</i> at increased risk: • Cancer • Chronic kidney disease • Chronic obstructive pulmonary disease • Heart conditions, such as heart failure, coronary artery disease, or cardiomyopathies • Immunocompromised state from solid organ transplant • Obesity (body mass index [BMI] ≥ 30 kg/m² but < 40 kg/m²) • Severe obesity (BMI ≥ 40 kg/m²) • Pregnancy • Sickle cell disease • Smoking • Type 2 diabetes mellitus
Comorbidity. Adults of any age with the following conditions <i>may be</i> at increased risk: • Asthma (moderate to severe) • Cerebrovascular disease (affects blood vessels and blood supply to the brain) • Cystic fibrosis • Hypertension or high blood pressure • Immunocompromised state from blood or bone marrow transplant, immune deficiencies, HIV, or use of corticosteroids or other immune-weakening medicines • Neurologic conditions, such as dementia • Liver disease • Overweight (BMI > 25 kg/m² but < 30 kg/m²) • Pulmonary fibrosis (having damaged or scarred lung tissues) • Thalassemia (a type of blood disorder) • Type 1 diabetes mellitus

Note: The CDC notes that at the time of this information, knowledge of the COVID-19 disease was evolving, and this list includes only conditions with sufficient evidence to draw conclusions.

Source: Coronavirus disease 2019 (COVID-19): People at increased risk. Centers for Disease Control and Prevention website. https://www.cdc.gov/coronavirus/2019-ncov/need-extra-precautions/index.html?CDC_AA_refVal=https%3A%2F%2Fwww.cdc.gov%2Fcoronavirus%2F2019-ncov%2Fneed-extra-precautions%2Fpeople-at-increased-risk.html. Updated November 30, 2020. Accessed December 7, 2020.

Safety

A single cough can launch virus-laden secretions at 50 mph, expelling close to 3,000 respiratory droplets. Coughing has long been recognized as a key vector of respiratory infections. A sneeze is even more powerful, forcing 100,000 droplets into the immediate environment at a speed of 100 mph.

Place a surgical mask on the patient and an N95 mask or HEPA respirator on yourself!

Words of Wisdom

The first vaccines to protect against COVID-19 infection were approved for use in the United States in December 2020. Although vaccine development for a new viral strain typically takes 1 decade or longer, the process was expedited in response to the COVID-19 pandemic, both by allocating vast resources to the vaccines' development and by capitalizing on research already completed on similar strains of the coronavirus.

including the United States, motivating EMS and health care facilities to prepare for further outbreaks. The incubation period is approximately 6 to 12 days after exposure; however, symptoms may not begin to appear for as long as 21 days after infection. Symptoms include watery diarrhea, vomiting, fever, body aches, and bleeding. The fatality rate can be as high as 70% if effective supportive treatment in an intensive care unit is not initiated promptly.¹⁶

If you suspect the patient may have this condition, place a surgical mask on the person and follow PPE precautions as outlined by local protocols and the CDC. Immediately notify the receiving facility that the patient may have or may have been exposed to the Ebola virus.

Words of Wisdom

Travel history should be a routine part of patient assessment.

Ebola

In 2014, an outbreak of the Ebola virus in West Africa caused international concern. Several infected people with the virus traveled to other countries,

Zika Virus

Zika virus is a vector-borne infection first noted in the United States in mid-2015. Cases are typically related to travel to areas where the Zika virus is prevalent. The virus is transmitted by the bite of the

YOU are the Provider

Part 4

On the basis of the patient's vital signs and physical examination, you elect to establish an IV line and administer a 250-mL bolus of normal saline. After you administer the bolus, you note that the patient's skin turgor is poor and that her skin is tenting. Because of this finding, you elect to administer a second 250-mL bolus of normal saline. On arrival at the ED, you give a report to the receiving nurse and prepare your unit for another call.

Recording Time: 12 Minutes

Respirations	20 breaths/min, normal
Pulse	Strong and regular, 100 beats/min
Skin	Warm and dry
Blood pressure	158/88 mm Hg
Oxygen saturation (SpO₂)	100% on room air
Pupils	PERRLA

7. What is the likely cause of the patient's hypertension?
8. With the administration of the second fluid bolus, which sounds should you listen for?

Aedes aegypti mosquito. There are multiple countries in the Caribbean and South America where the virus is prevalent, and certain areas in the continental United States and Puerto Rico. South Florida and Brownsville, Texas, are two areas in the United States where travel precautions are advised.¹⁷ There is no vaccine for the virus, and prevention is aimed at protecting against mosquito bites.¹⁸

According to the CDC, most people infected with Zika virus present with few or no symptoms.¹⁹ The most common symptoms of Zika include fever, rash, joint pain, and conjunctivitis. Other symptoms may include muscle pain and/or headache. Symptoms are usually mild and last from several days to a week. Zika virus can be diagnosed with a urine or blood test.²⁰

The most significant complication of Zika virus affects pregnant women.²¹ The fetus is at risk for serious birth defects, including microcephaly, in which the baby's head is small because the brain has not properly developed or stops growing after birth.²² Other than mother to fetus, the most common route of human-to-human transmission is through sexual contact.¹⁸

There have been no documented cases of blood transfusion transmission of Zika virus in the United States, but there have been cases of transmission through platelet transfusions in Brazil.²³ All blood donations in the United States are screened for Zika virus, and potential donors are questioned about travel to areas where the virus is prevalent.

Care is supportive. Place the patient in a position of comfort and provide oxygen and IV fluids as needed. Question travel history for any patient suspected of having Zika virus. Use routine standard precautions for patient care. There are currently no recommendations for special protective equipment for medical personnel, except to prevent person-to-person transmission through blood or body fluids.

Travel Medicine

Every day, thousands of people travel to various countries. Although humans share many common germs, some are confined to certain areas of the world. As an EMS provider, you must be aware of this when assessing a patient who recently traveled outside the United States.

Patients who acquire an illness from another country can present with a variety of symptoms,

depending on the illness. They may have a fever, cough, vomiting, bloody diarrhea, body aches, or rashes. In many cases, the patient experiences mild symptoms and does not require EMS care. However, some patients become extremely ill, requiring urgent evaluation and treatment. When you encounter an ill patient with a recent travel history, place a mask on the patient and gather as much information as possible. Important questions to ask the patient include the following:

- Where did you recently travel?
- Did you receive any vaccinations before your trip?
- Were you exposed to any infectious diseases?
- Is there anyone else in your travel party who is sick?
- Which types of food did you eat?
- What was your source of drinking water?

If you suspect the patient has a communicable illness, follow appropriate PPE precautions and notify the receiving facility. Although treatment for many travel-related illnesses is primarily supportive in the prehospital environment, always be prepared to manage life-threatening conditions should the patient become unstable.

Conclusion

Although trauma patients often present with dramatic signs and symptoms, the assessment and treatment you provide for them are fairly straightforward. The assessment and treatment of medical patients, by comparison, can be very challenging, and the medical patient's condition may not be as readily apparent as in a trauma patient. Therefore, treatment may not be as straightforward. You must remember that delays of any kind while attempting to diagnose a condition can be harmful to the patient and thus are not recommended. Your best approach is to keep calm, use your patient assessment skills, treat the patient's symptoms while maintaining a high index of suspicion for underlying problems, report to medical control, and transport the patient safely to the closest most appropriate facility. Finally, keep in mind that patients sometimes have more than one isolated problem, so you must be prepared to handle any combination of conditions, including conditions of medical patients who have been involved in traumatic situations.

YOU are the Provider SUMMARY**1. Which systems of the body may be causing the patient's signs and symptoms?**

This patient's symptoms could be the result of a gastrointestinal problem such as appendicitis or diverticulitis. They could also be a result of reproductive problems such as pelvic inflammatory disease or another sexually transmitted disease. A urinary problem such as a kidney stone is another possibility. On the basis of the patient's history and physical examination, a kidney stone should be high on your list of probabilities.

2. Does this patient require immediate transport?

This patient does not require immediate transport. You do not note any immediate life threats, so you should spend time on scene continuing your assessment and performing any treatment you may elect to initiate.

3. What are some other pertinent questions that you may want to ask the patient?

You may want to ask questions about the patient's sexual history. Is she still sexually active? Is she in a monogamous relationship? If so, is her partner also monogamous? Does she still have her menstrual cycle? If so, when was her last cycle and was it normal for her? Does she have a medical history of sexually transmitted diseases? You may also want to further question the patient regarding her urinary output; specifically, the frequency, color, and any associated odors. All of these questions will assist you in narrowing down the specific medical cause or causes.

4. On the basis of the patient's presentation, what do you suspect is the most likely cause of her discomfort?

This patient presents with typical signs and symptoms of a kidney stone. The flank pain is a result of the stone traveling in the kidney, and the pain on urination is from the stone attempting to pass through the ureter. Based on the length of transport, you may want to consider a paramedic intercept for the administration of pain medications.

5. Does this patient require an IV line?

On the basis of the patient's statement that she has not had adequate fluid intake for 3 days, the patient is most likely dehydrated and would benefit from IV fluid administration. Fluid may also help to flush out the stone. Because of the patient's age and lack of a cardiac history, you recognize that the risk of pulmonary edema with a 250-mL fluid bolus is very small. Nonetheless, it is prudent to listen to lung sounds to exclude fluid overload after administration of the second 250-mL bolus.

6. Does this patient require treatment at a specific hospital, or should you transport her to the closest community hospital?

This patient should be transported to the closest hospital. There is no increased benefit in transporting her to a specialty hospital. The local community hospital should have the appropriate resources to treat a common problem such as a kidney stone.

7. What is the likely cause of the patient's hypertension?

The cause of this patient's hypertension can likely be attributed to one of two causes. The first potential cause is the severe pain that the patient is experiencing; pain and anxiety are common causes of elevated blood pressure. The second cause might be chronic, undiagnosed hypertension. In other words, this may be the patient's normal blood pressure.

8. With the administration of the second fluid bolus, which sounds should you listen for?

With the administration of IV fluid, the AEMT would want to pay careful attention to the patient's lung sounds. In a patient with a history of pulmonary edema (either diagnosed or undiagnosed), the administration of two fluid boluses may exacerbate the condition, causing an increase in the work of breathing.

Narrative

EMS dispatched to 474 Big Mountain Road for a 47-year-old woman with flank pain and difficulty with urination. On arrival, met by husband who directs us to the patient, who is found lying in bed in the fetal position. Patient is AO × 4, ABCs intact, complains of sharp, stabbing pain in right-side flank area for 3 days. Further states pain on urination that radiates to her groin in "waves," which has decreased her fluid intake. Complains of 10/10 pain. No past medications or known allergies. Past medical history of kidney stones 13 years ago, but states this pain is worse. Remainder of physical exam is unremarkable, with the exception of poor skin turgor and tenting. Consent obtained for treatment and transport. Assisted patient to cot, secured on left side per patient request. Transported to Pembina County Memorial Hospital (PCMH), nonemergent. En route: Vitals as above. 18-ga IV established to right hand with 250-mL NS bolus. After bolus, patient still shows signs of dehydration. Additional 250-mL bolus administered. On arrival at PCMH, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- Trauma emergencies are injuries that are the result of physical forces applied to the body. Medical emergencies require EMS attention because of illnesses or conditions not caused by an outside force.
- The assessment of a medical patient is similar to that of a trauma patient but with a different focus. Whereas a trauma assessment focuses on physical injuries, most of which are visible through a physical examination, medical patient assessment is usually more focused on symptoms and depends more on establishing an accurate medical history.
- Evaluation of the NOI for a medical patient can provide an index of suspicion for different types of serious or life-threatening underlying illnesses.
- For responsive medical patients, obtaining a thorough patient history can be one of the most beneficial aspects of the patient assessment. Try to determine the NOI by asking questions about the patient's chief complaint.
- Responsive medical patients seldom need a full-body exam, but all should get a focused examination based on their chief complaint. On the other hand, you should always perform a full-body exam on unresponsive patients; this head-to-toe assessment may give you clues to help identify the problem. Your secondary assessment of an unresponsive or unstable patient should never delay transport.
- Most medical emergencies require a level of treatment beyond what is available in the prehospital setting. Also, the treatments depend on an accurate diagnosis of the exact medical condition; therefore, advanced testing in the hospital may be required.
- If the patient is not in critical condition, you should gather as much important information as possible from the scene so that you can transmit that information to the physician at the ED.
- Written protocols may allow the AEMT to administer certain medications without calling for online medical control, so it is important to be familiar with the guidelines for your EMS agency.
- Many medical patients will benefit from being transported to a specific hospital capable of handling their particular condition; for example, a patient with myocardial infarction may need a facility that is capable of performing heart catheterization, and a patient experiencing a stroke may need a facility with a designated stroke team.
- Because it is often impossible to tell which patients have infectious diseases, you should avoid direct contact with the blood and body fluids of all patients. Always wear gloves, cover any open wounds you may have, wash hands properly and frequently, routinely clean your vehicle after transport, and take great care in handling and disposing of needles. Be sure to follow the proper steps when dealing with potential exposure situations.
- If you think you may have been exposed to an infectious disease, or you are stuck with a needle or injured in some other way while caring for a patient who might have a disease of concern, see your physician (or your employer's designated physician) immediately.
- AEMTs are especially likely to encounter certain infectious diseases, including HIV, influenza, hepatitis, herpes simplex, syphilis, meningitis, tuberculosis, pertussis, and methicillin-resistant *S aureus*.
- Patients with HIV infection or hepatitis may be asymptomatic or have a variety of signs and symptoms. Prehospital treatment is supportive.
- AIDS is the end-stage disease process caused by HIV. A patient with AIDS is extremely vulnerable to infection, so it is important to protect the person from contracting additional infections.

- There is no vaccine to protect against HIV infection, but it is only a potential hazard when deposited on a mucous membrane or directly into the bloodstream.
- There is no sure way to tell which patients have a contagious form of hepatitis. Vaccination with hepatitis B vaccine is highly recommended for AEMTs.
- Newly recognized or emerging diseases include Hantavirus, enteropathogenic *E coli*, West Nile

virus, severe acute respiratory syndrome, and avian flu. Some of these diseases were first noted outside the United States, but have since become established in US vectors.

- Global health issues include Middle East respiratory syndrome coronavirus, COVID-19, and Ebola. When these diseases are suspected, travel history may provide valuable insights into the patient's condition.

Vital Vocabulary

acquired immunodeficiency syndrome

(AIDS) The end-stage disease process caused by the human immunodeficiency virus (HIV). A person with AIDS is extremely vulnerable to numerous infections.

epidemic An outbreak of a disease in which new cases in a human population substantially exceed the number expected based on recent experience.

hepatitis Inflammation of the liver, usually caused by a viral infection, that causes fever, loss of appetite, jaundice, fatigue, and altered liver function.

herpes simplex A common virus caused by human herpes viruses 1 and 2, characterized by small blisters whose location depends on the type of virus. Type 2 results in blisters on the genital area, while type 1 results in blisters on non-genital areas.

human immunodeficiency virus (HIV) The virus that causes infection and ultimately causes acquired immunodeficiency syndrome (AIDS), which damages the cells in the body's immune system so that the body is unable to fight infection or certain cancers.

index of suspicion Awareness that unseen serious and/or life-threatening injuries may exist when determining the mechanism of injury.

influenza A virus that has crossed the animal/human barrier and infected humans and that kills thousands of people every year.

medical emergencies Emergencies caused by illnesses or conditions, not by an outside force.

meningitis An inflammation of the meningeal coverings of the brain and spinal cord; it is usually caused by a virus or a bacterium.

meningococcal meningitis An inflammation of the meningeal coverings of the brain and spinal cord; can be highly contagious.

methicillin-resistant *Staphylococcus aureus*

(MRSA) A bacterium that can cause infections in different parts of the body and is often resistant to commonly used antibiotics; it is transmitted by different routes, including the respiratory route, and can be found on the skin, in surgical wounds, and in the bloodstream, lungs, and urinary tract.

nature of illness (NOI) The general type of illness a patient is experiencing.

nosocomial Hospital acquired.

pandemic An outbreak of a disease that occurs on a global scale or over a wide area.

pertussis An airborne bacterial infection that affects primarily children younger than 6 years; patients will be feverish and exhibit a "whoop" sound on inspiration after a coughing attack; highly contagious through droplet infection; also called whooping cough.

severe acute respiratory syndrome (SARS) A potentially life-threatening viral infection that usually starts with flulike symptoms.

sign An objective finding that can be seen, heard, felt, smelled, or measured (eg, a laceration

or the patient's blood pressure) when assessing a patient to establish illness or injury.

symptom Information that is told to you but that cannot be seen, such as the symptoms a patient describes.

trauma emergencies Emergencies that are the result of physical forces applied to the body; injuries.

tuberculosis A chronic bacterial disease, caused by *Mycobacterium tuberculosis*, that usually affects the lungs but can also affect other organs

such as the brain and kidneys; it is spread by cough and can lie dormant in a person's lungs for decades and then reactivate.

virulence A measure of the disease-causing ability of a microorganism.

Zika A type of virus that is transmitted by the *Aedes aegypti* mosquito in which the majority of infected persons are asymptomatic; transmission can occur from an infected mother to her fetus, and from an infected male to his sexual partners.

Chapter 17

Respiratory Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Respiratory

Anatomy, signs, symptoms, and management of respiratory emergencies including those that affect the

- Upper airway (pp 882–890, 923–924, 927)
- Lower airway (pp 887, 904, 923–924)

Anatomy, physiology, pathophysiology, assessment, and management of

- Epiglottitis (pp 903, 928)
- Spontaneous pneumothorax (pp 899, 926–927)

- Pulmonary edema (pp 895–896, 924)
- Asthma (pp 898, 925–926)
- Chronic obstructive pulmonary disease (pp 896–898, 924–925)
- Environmental/industrial exposure (pp 901–902, 927–928)
- Toxic gas (pp 901–902)
- Pertussis (pp 903, 928–929)
- Cystic fibrosis (p 902)
- Pulmonary embolism (pp 900–901, 927)
- Pneumonia (pp 897, 903, 928)
- Viral respiratory infections (pp 902–903)
- Obstructive/restrictive disease (pp 896–898, 905, 924–926)

KNOWLEDGE OBJECTIVES

1. Review the structures and functions of the upper and lower airways, lungs, and accessory structures of the respiratory system. (pp 882–885)
2. Explain the physiology of respiration and list the signs of normal breathing. (pp 885–887)
3. Explain the special patient assessment and care considerations that are required for pediatric patients who are experiencing respiratory distress. (pp 906–907)
4. Discuss the pathophysiology of respiration and provide examples of the common signs and symptoms a patient with inadequate breathing may present with in an emergency situation. (pp 887–889)
5. Explain the concept of hypoxic drive. (p 889)
6. Describe the various respiratory conditions that cause dyspnea, including their causes, assessment findings and symptoms, complications, and specific prehospital management and transport decisions. (pp 891–892)
7. List and review the characteristics of infectious diseases that are frequently associated with dyspnea. (pp 892–895)
8. Explain the special patient assessment and care considerations that are required for geriatric patients who are experiencing respiratory distress. (pp 906–907)

9. Describe the assessment of a patient who is in respiratory distress and the relationship of the assessment findings to patient management and transport decisions. (pp 906–907)
10. Describe the primary emergency medical care of a person who is in respiratory distress. (pp 906–907)
11. List and define five different types of adventitious breath sounds, their signs and symptoms, and the disease process associated with each one. (p 909)
12. Summarize the steps in emergency medical care of a patient with dyspnea. (pp 915–916)
13. State the generic name, medication forms, dose, administration, indications, actions, and contraindications for medications that are administered via metered-dose inhalers and small-volume nebulizers. (pp 917–921)
14. Discuss the application of a continuous positive airway pressure/bilevel positive airway pressure unit. (pp 922–923)
15. Discuss some epidemic and pandemic considerations related to the spread of influenza type A and strategies advanced emergency medical technicians should use to protect themselves from infection during a possible crisis situation. (pp 929–931)

SKILLS OBJECTIVES

1. Demonstrate the process of history taking to obtain more information related to a patient's chief complaint based on a case scenario. (pp 909–915)
2. Demonstrate how to use the OPQRST-I assessment to obtain more specific information about a patient's breathing problem. (p 910)
3. Demonstrate how to assist a patient with the administration of a small-volume nebulizer. (pp 918–919)
4. Demonstrate how to assist a patient with the administration of a metered-dose inhaler. (pp 920–921)

Introduction

Dyspnea, or difficulty breathing, is a complaint that you will encounter often. It is a symptom of many different conditions, from the **common cold** and **asthma** to heart failure and **pulmonary embolism**. Several different problems occurring at the same time may contribute to a patient's dyspnea, including some that are serious or life threatening. You may or may not be able to determine the cause of dyspnea in a particular patient. Regardless, you may still be able to save a life.

This chapter begins with a basic explanation of how the lungs function. It then looks at common medical problems that can impede normal functioning and cause dyspnea, including acute pulmonary edema, chronic obstructive pulmonary disease (COPD), and asthma. You will learn the signs and symptoms of each condition. You should keep all of these possible medical problems in mind as you obtain the patient's medical history and perform a physical assessment. The information that you obtain will help you determine the best treatment, which may differ based on the underlying cause of the dyspnea.

Remember, the sensation of not getting enough air can be terrifying, regardless of its cause. As an advanced emergency medical technician (AEMT), you must be prepared to treat not only the patient's symptoms and underlying problem, but the anxiety produced as well.

Anatomy and Physiology Review

Anatomy Review

The respiratory system consists of all the structures of the body that contribute to the breathing process. The upper airway includes all anatomic airway structures above the level of the vocal cords. Air flows through the structures shown in **FIGURE 17-1**. See Chapter 11, *Airway Management*, for an in-depth discussion of the anatomy and physiology of the respiratory system.

Gas exchange is the process by which deoxygenated blood from the pulmonary circulation releases carbon dioxide and is resupplied with oxygen before it enters the cardiac circulation. This process occurs at the level of the alveoli, the tiny air sacs

FIGURE 17-1 The upper airway includes the nasopharynx, nasal air passages, pharynx, mouth, oropharynx, and epiglottis. The larynx is considered the dividing line between the upper and lower airways. The lower airway includes the trachea, alveoli, bronchioles, and main bronchi.

clustered around the terminal bronchioles in the lungs (**FIGURE 17-2**). These terminal bronchioles are very thin and have little structure. This is helpful for gas exchange, but it also means that these

bronchioles lack cilia, a mucous blanket, smooth muscle, or rigid structures.

The pulmonary circulation begins at the right ventricle, where the pulmonary artery (the

only artery that primarily carries deoxygenated blood) branches into increasingly smaller vessels until it reaches the pulmonary capillary bed, which surrounds the alveoli and terminal bronchioles (FIGURE 17-3). There is substantially

more circulation to the lung bases than there is to the lung apices. Because humans are upright, gravity-dependent creatures, most infections and pathologic conditions occur at the base of the lung.¹

FIGURE 17-3 Pulmonary circulation begins as blood leaves the right ventricle via the pulmonary artery. The pulmonary capillary bed brings red blood cells close to the terminal bronchioles. After picking up oxygen, the blood returns to the left atrium via the pulmonary veins.

YOU are the Provider

Part 1

Medic One is requested to respond to an assisted living center for a patient with difficulty breathing. You and your partner are greeted by the staff who state that the 86-year-old patient has been getting progressively worse over the past couple of days. They suggested she go to the hospital at the onset of symptoms, but the patient kept insisting that it would “get better” after her oxygen was increased and she used her “puffer.” The patient has a history of hypertension, emphysema, and asthma. She is currently on oxygen at 4 L/min via nasal cannula.

1. What are some potential causes of shortness of breath in older adults?
2. What equipment would you need immediately after you arrive on scene?

Special Populations

The anatomy of the respiratory system in children is proportionately smaller and less rigid than that in an adult (**FIGURE 17-4**). A child's nose and mouth are much smaller than those of an adult. The larynx, cricoid cartilage, and trachea are smaller, softer, and more flexible as well. This makes the mechanics of breathing much more delicate. A child's pharynx is also smaller and less deeply curved. The tongue takes up proportionately more space in a child's mouth than in an adult's mouth.

These anatomic differences are important for your assessment. For example, the smaller larynx of a child becomes obstructed more easily. The chest wall in children is softer; therefore, children depend more heavily on the diaphragm for breathing. You will notice that the abdomen moves in and out considerably with each breath, especially in an infant. Young infants do not know how to breathe through the mouth. Therefore, as you assess an infant or a child, you must carefully consider these differences.

FIGURE 17-4 The respiratory system of a child is proportionately smaller and less rigid than that of an adult.

Physiology Review

Respiration

The principal function of the lungs is **respiration**, which is the exchange of oxygen and carbon dioxide. The two processes that occur during respiration are inspiration (inhaling) and expiration (exhaling).

Ventilation is the mechanical process of moving air into and out of the lungs for gas exchange. During pulmonary respiration, oxygen is provided to the blood, and carbon dioxide is removed from it. Oxygen entering the alveoli from inhalation passes through tiny passages in the alveolar wall into the capillaries, which carry the oxygen to the heart. The heart, in turn, pumps oxygenated blood throughout the body. Carbon dioxide produced by the body's cells (**FIGURE 17-5A**) returns to the lungs in the blood that circulates through and around the alveolar air spaces. The carbon dioxide diffuses

A

B

FIGURE 17-5 The exchange of oxygen and carbon dioxide during respiration. **A.** Oxygen passes from the blood through capillaries to tissue cells. Carbon dioxide passes from tissue cells through capillaries to the blood. **B.** In the lungs, oxygen is picked up by the blood and carbon dioxide is given off.

© Jones & Bartlett Learning.

back into the alveoli and travels back up the bronchial tree and out the upper airways during exhalation (FIGURE 17-5B). Again, carbon dioxide is “exchanged” for oxygen, which travels in exactly the opposite direction (during inhalation).

Words of Wisdom

Ventilation is the act of air going into and out of the lungs. Respiration is the exchange of gases at the pulmonary or cellular level.

Inspiration

The stimulus to breathe comes from the respiratory center located in the medulla. The involuntary control of breathing originates in the brainstem, specifically in the pons and medulla. The impulses for automatic breathing descend through the spinal cord and can be overridden (to a point) by voluntary control. The motor nerves of respiration are the phrenic nerves, which innervate the diaphragm, and the intercostal nerves, which innervate the external intercostal muscles (muscles between the ribs).

During inspiration, the diaphragm and intercostal muscles contract, causing the diaphragm to flatten and the ribs to move up and out. The combined actions of these structures enlarge the thorax in all directions, causing intrapulmonary pressure to fall slightly below atmospheric pressure (the air pressure outside the body). As the diaphragm and intercostal muscles contract and the thoracic cage expands, air pressure within the thorax decreases, creating a slight vacuum. This pulls air in through the trachea and fills the lungs, inflating the alveoli. When the air pressure outside the thorax equals the air pressure inside the thorax, air stops moving, and a person stops inhaling. Oxygen and carbon dioxide are then able to diffuse across the alveolar membrane from an area of higher pressure to an area of lower pressure until the pressures are equal. Normal inspiratory reserve volume, the amount of air that can be inhaled in addition to normal tidal volume (about 500 mL), is about 3,000 mL in a typical adult male and 2,300 mL in a typical adult female.

Expiration

As the chest expands, mechanical receptors, known as stretch receptors, in the chest wall and bronchioles send a signal to the apneustic center, located in the pons, via the vagus nerve to inhibit the inspiratory center, and expiration occurs. This feedback loop, a combination of mechanical and neural control, is known as the **Hering-Breuer reflex** and terminates inhalation to prevent overexpansion of the lungs. The diaphragm and intercostal muscles relax, moving the ribs down and in and the diaphragm back into its dome shape, which increases intrapulmonary pressure. The natural elasticity, or recoil, of the lungs passively removes the air. Normal expiratory reserve volume, the amount of air that can be exhaled following normal exhalation, is about 1,200 mL.

Normally, expiration lasts twice as long as inspiration. This relationship is expressed by the **inspiratory/expiratory (I/E) ratio**; a normal I/E ratio is 1:2. When a patient has an obstructed lower airway and is having difficulty getting air out (such as in asthma), the expiratory phase is prolonged and may be four to five times as long as inspiration. In the case of a patient with asthma, the I/E ratio would be 1:4 or 1:5. In a patient with **tachypnea** (rapid respiratory rate), the expiratory phase is short and approaches that of inspiration; the I/E ratio may be 1:1.

TABLE 17-1 lists the characteristics of adequate breathing, and **TABLE 17-2** lists characteristics of inadequate breathing.

TABLE 17-1 Signs of Normal Breathing
• A normal rate (adult: 12 to 20 breaths/min; child: 15 to 30 breaths/min; infant: 25 to 50 breaths/min) • A regular pattern of inhalation and exhalation • Clear and equal breath sounds on both sides of the chest • Regular and equal chest rise (chest expansion) and fall • Adequate depth (tidal volume) • Unlabored; without adventitious breath sounds (abnormal breath sounds) (wheezing, stridor)

Note: Respiratory ranges are per the NHTSA 2009 EMT National EMS Education Standards. Ranges presented in other sources may vary.

Pediatric data from: American Heart Association (AHA). Vital signs in children. In: *Pediatric Advanced Life Support*. Dallas, TX: AHA; 2015.

TABLE 17-2 Signs and Symptoms of Inadequate Breathing

Dyspnea or shortness of breath
An altered mental status associated with shallow or slow breathing
The adult patient appears anxious or restless; the pediatric patient appears sleepy or listless.
The respiratory rate is too fast or too slow.
The breathing rhythm is irregular.
The skin is pale, cool, clammy, or cyanotic.
Adventitious breath sounds are heard, including wheezing, gurgling, snoring, crowing, or stridor (harsh, high-pitched, barking sounds).
Decreased or noisy breath sounds are heard on one or both sides of the chest.
An inability to speak more than a few words between breaths (two- to three-word dyspnea). Ask the patient “How are you doing?” A patient who cannot speak at all most likely has a respiratory emergency.
Accessory muscle use, retractions , or labored breathing
Unequal or inadequate chest expansion
Coughing excessively
The patient is sitting up, leaning forward with palms flat on the bed or the arms of the chair. This is called the tripod position because the patient’s back and both arms are working together to support the upper body.
Pursed lips (pursed lip breathing) or nasal flaring

© Jones & Bartlett Learning.

Pathophysiology

For the body to receive the required nutrients and oxygen and to dispose of waste products, adequate ventilation, **diffusion**, and **perfusion** must occur. There are multiple complications that interfere with an ample intake of oxygen. These can be separated into four areas:

1. Upper airway obstruction may be from a foreign body obstruction, trauma, or an inflammation such as tonsillitis or **epiglottitis**.
2. Lower airway obstruction may be caused by trauma. Obstructive lung disease and other

complications, such as mucus accumulation, smooth-muscle spasm, and airway edema, can also create narrowing and blockage of the lower airways.

3. Chest wall impairment is another cause of impaired ventilation. Trauma, hemothorax, **pneumothorax**, empyema (**pleural effusion**), pleural inflammation, and neuromuscular diseases such as multiple sclerosis or muscular dystrophy prevent adequate chest wall excursion.
4. Problems in neurologic control can impair ventilation. These include brainstem malfunction from central nervous system–depressant drugs, stroke or other medical neurologic condition, or trauma. Trauma and neuromuscular diseases can also cause phrenic or spinal nerve dysfunction, preventing normal neurologic control. By rapidly assessing the patient and providing the necessary interventions, problems associated with oxygenation and ventilation can be minimized or avoided altogether.

Regardless of the reason for breathing difficulty, the critical issue is that you must be able to immediately recognize the signs and symptoms of inadequate breathing and know what to do. **TABLE 17-3** provides key signs and symptoms to help you recognize and differentiate between different respiratory complaints.

Gas Exchange Interface

It is often helpful to think of alveoli as small balloons at the end of a straw. Alveoli are made up of two types of cells:

1. Type I alveolar cells (pneumocytes) are almost empty, allowing for better gas exchange. They lack cellular components that would permit them to reproduce.
2. Each alveolus has several type II pneumocytes, which can make new type I cells and produce a substance known as surfactant, which reduces surface tension and helps keep the alveoli expanded. When alveoli are damaged by infection, cigarette smoking, or other trauma, their ability to repair themselves correlates directly to the number of type II cells that remain. After all type II cells in an alveolus have been destroyed, the alveolus cannot make new cells or surfactant and is essentially dead.

TABLE 17-3 Signs and Symptoms Seen in Various Respiratory Conditions

Condition	Signs and Symptoms	Condition	Signs and Symptoms
Asthma	• Wheezing on inspiration/expiration • Bronchospasm	Epiglottitis	• Dyspnea • High fever • Stridor • Drooling • Difficulty swallowing • Severe sore throat • Tripod or sniffing position
Anaphylaxis	• Flushed skin or hives (urticaria) • Generalized edema • Decreased blood pressure (hypotension) • Laryngeal edema with dyspnea • Wheezing or stridor	Influenza type A (flu)	• Cough • Fever • Sore throat • Fatigue
Bronchiolitis	• Shortness of breath • Wheezing • Coughing • Fever • Dehydration • Tachypnea • Tachycardia	Pertussis (whooping cough)	• Coughing spells • “Whooping” sound • Fever
Bronchitis	• Chronic cough (with sputum production) • Wheezing • Cyanosis • Tachypnea (increased breathing rate)	Pneumonia	• Dyspnea • Chills, fever • Cough • Green, red, or rust-colored sputum • Localized wheezing or crackles
Heart failure	• Dependent edema • Crackles (pulmonary edema) • Orthopnea • Paroxysmal nocturnal dyspnea	Pneumothorax	• Sudden chest pain with dyspnea • Decreased breath sounds (affected side) • Subcutaneous emphysema
Common cold	• Cough • Runny or stuffy nose • Sore throat	Pulmonary embolus	• Sharp chest pain • Sudden onset • Dyspnea • Tachycardia • Clear breath sounds initially
Croup	• Fever • Barking cough • Stridor • Mostly seen in pediatric patients	Tension pneumothorax	• Severe shortness of breath • Decreased/altered level of consciousness • Neck vein distention • Tracheal deviation (late sign) • Hypotension; signs of shock (late sign)
Diphtheria	• Difficulty breathing and swallowing • Sore throat • Thick, gray buildup in throat or nose • Fever	Respiratory syncytial virus (RSV)	• Cough • Wheezing • Fever • Dehydration
Emphysema	• Barrel chest • Pursed lip breathing • Dyspnea on exertion • Cyanosis • Wheezing/decreased breath sounds	Tuberculosis	• Cough • Fever • Fatigue • Productive/bloody sputum

Alveoli function best when they are kept partially inflated. Blowing up a balloon takes a lot of pressure. After the balloon is partially inflated, however, it is much easier to inflate it the rest of the way. The same is true of alveoli. By reducing the surface tension of the alveoli, surfactant makes it easier for them to expand. When surfactant is washed out of the alveoli, as may occur in pulmonary edema, submersion incidents, or severe shock, they are much more likely to collapse.

After foreign material gets into the terminal bronchioles and alveoli, it typically never comes out. Emphysema may affect this area of the lung, damaging or destroying the few structural components that are present. When that happens, the terminal branches of the tracheobronchial tree become so weak that they collapse during exhalation and trap air in the alveoli.

Collapsed, fluid-filled, or pus-filled alveoli do not participate in gas exchange. Instead, these alveoli contribute to a shunt, in which blood from the right side of the heart bypasses the alveoli and returns to the left side of the heart in an unoxygenated state, perhaps resulting in hypoxemia. Conditions related to ventilation, perfusion, or both can prevent oxygen from reaching the bloodstream.

Like all capillaries in the body, the pulmonary capillaries are narrow and normally allow red blood cells to pass through only in single file. People with chronic lung disease and chronic **hypoxia** often generate a surplus of red blood cells over time, which makes their blood thick (polycythemia). Viscous blood that is pushed through the tiny pulmonary capillaries can place a substantial strain on the right side of the heart. When the alveoli are distended by COPD, they push against the capillary bed, further narrowing the capillaries and straining the right side of the heart. Right-side heart failure because of chronic lung disease is known as *cor pulmonale*. It may also occur as a result of any condition that increases the pressure in the pulmonary arterial system.

Words of Wisdom

The body's immediate response to mild hypoxemia is to increase the heart rate (possibly to a rate of more than 130 beats/min, or tachycardia). Severe hypoxia often causes bradycardia. Any uncorrected hypoxic insult may trigger a lethal cardiac dysrhythmia, such as ventricular fibrillation or ventricular tachycardia.

Carbon Dioxide Retention and Hypoxic Drive

You will sometimes encounter patients who have an elevated level of carbon dioxide in their arterial blood. The level can rise for several reasons. Various types of lung disease may impair the exhalation process. The body may also produce too much carbon dioxide, either temporarily or chronically, depending on the disease or abnormality. If, over a period of years, arterial carbon dioxide levels rise slowly to an abnormally high level and remain there (as in late COPD), the respiratory centers in the brain, which sense carbon dioxide levels and control breathing, may work less efficiently.

The failure of those centers to respond normally to a rise in arterial levels of carbon dioxide is a result of chronic **carbon dioxide retention**. Recall that normally, chemoreceptors sense the levels of carbon dioxide (based on the pH) in the blood and cerebrospinal fluid. When carbon dioxide levels become elevated, the respiratory centers in the brain increase the rate and depth of ventilation accordingly. However, patients with chronic lung diseases have difficulty eliminating carbon dioxide through exhalation; thus, they always have higher levels of carbon dioxide. The theory is that the brain gradually accommodates high levels of carbon dioxide and then uses a “backup system” to control breathing based on low levels of oxygen, rather than high levels of carbon dioxide. This condition is called **hypoxic drive**.

In these patients, the stimulus to breathe is the detection of low blood oxygen levels. If the arterial level of oxygen is increased, as happens when the patient is given additional oxygen, there is less stimulus to breathe; both the high carbon dioxide and low oxygen drives are decreased. Therefore, giving too much oxygen to these patients may depress, or completely stop, the respirations. However, as will be discussed later in this chapter, you should never withhold oxygen from a patient who needs it.

Special Populations

People older than 65 years are especially susceptible to problems with respiration, from occult (not obvious) stroke, lung disease, cardiovascular disease, liver disease, or certain medications.²

Hypoventilation

When the lungs fail to work properly, the body cannot efficiently dispose of carbon dioxide, and it accumulates in the blood. The excess carbon dioxide combines with water to form bicarbonate ions and hydrogen (H⁺) ions, also known as carbonic acid (H₂CO₃). The result is **respiratory acidosis**.

Acidosis can occur if **hypoventilation** is not recognized. Impaired ventilation can be attributed to a variety of factors, as shown in **TABLE 17-4**.

Recall that pH is an inverse expression of how many free hydrogen ions (H⁺) are in a solution. Thus, the carbon dioxide level in the blood is also directly related to pH (acid-base balance). Patients who are hyperventilating usually have respiratory alkalosis with a high pH. As their carbon dioxide level decreases, their pH level rises. Patients who are hypoventilating usually have respiratory acidosis. As their carbon dioxide level increases, their pH level decreases.

Many types of problems can cause patients to hypoventilate:

- **Conditions that impair lung function.** When a patient is breathing but gas exchange is impaired, the carbon dioxide level in the blood rises. This situation can occur in patients with

severe atelectasis, pneumonia, pulmonary edema, asthma, and COPD.

- **Conditions that impair the mechanics of breathing.** Gas flow can be suppressed by a high cervical fracture with chest wall paralysis, flail chest, diaphragmatic rupture, severe retractions, an abdomen full of air or blood, abdominal or chest binding (using a pneumatic antishock garment or immobilization straps), and anything else that restricts the pressure changes that facilitate respiration.

Obesity hypoventilation syndrome (also known as pickwickian syndrome) is respiratory compromise related to morbid obesity. One of the earliest descriptions of the combination of obesity, respiratory compromise, and sleep apnea is found in the character of Joe the “fat boy” in Charles Dickens’s *Pickwick Papers*. Joe would fall asleep in midsentence, snore loudly, and generally have signs of hypercapnia. This syndrome is becoming more common, given the nationwide increase in the occurrence of obesity.

- **Conditions that impair the neuromuscular apparatus.** A patient who has experienced head trauma, an intracranial infection, or a brain tumor may have sustained damage to the respiratory centers of the brain, which may then compromise ventilation. Other conditions also may impair the neuromuscular apparatus:
 - Serious injury to the spinal cord (above the level of the fourth cervical vertebra [C4]) may block the nerve impulses that stimulate breathing.
 - **Guillain-Barré syndrome**, characterized by progressive muscle weakness and paralysis advancing from the hands and feet, can result in ineffective breathing if the paralysis reaches the diaphragm.
 - Amyotrophic lateral sclerosis (ALS; also known as Lou Gehrig disease) also causes progressive muscle weakness. This disease is progressive, with death usually attributable to respiratory failure as the muscles of respiration become unable to maintain adequate ventilation.
 - **Botulism** is caused by the bacterium *Clostridium botulinum*. This somewhat rare disease is usually caused by food poisoning

TABLE 17-4 Selected Causes of Impaired Ventilation	
Category	Conditions
Upper airway obstruction	Foreign body obstruction Infection Trauma
Lower airway obstruction	Trauma Obstructive disease Increased mucus production Airway swelling (edema)
Chest wall impairment	Pneumothorax Flail chest Pleural effusion Restrictive disease (scoliosis, kyphosis)
Neuromuscular impairment	Overdose Lou Gehrig disease (amyotrophic lateral sclerosis) Carbon dioxide narcosis

or by giving infants raw (unpasteurized) honey, which may be contaminated with spores of the bacterium. Botulism can cause muscle paralysis and is usually fatal when it reaches the muscles of respiration.

- **Conditions that reduce respiratory drive.** The stimulus to breathe is often called respiratory drive. Anything that interrupts or decreases the involuntary stimulus to breathe can result in hypoventilation or even apnea. Perhaps the most common hypoventilation crisis emergency medical services (EMS) providers see is acute opioid narcotic overdose (heroin, for example). Intoxication with alcohol, narcotics, and a host of other drugs and toxins can reduce the respiratory drive. Head injury, hypoxic drive, and asphyxia are all associated with grossly low respiratory rate and volume. The ultimate expression of hypoventilation is respiratory arrest followed by cardiac arrest.

In these circumstances, aggressive treatment must be initiated to assist the patient's respiratory efforts.

Hyperventilation

Hyperventilation is defined as overbreathing to the point that the level of arterial carbon dioxide falls below normal. This may be an indicator of a major, life-threatening illness. For example, a patient with diabetes who has an extremely high blood glucose level, a patient who has taken an overdose of aspirin, or a patient with a severe infection is likely to hyperventilate. In these cases, rapid, deep breathing is the body's attempt to compensate for acidosis, the buildup of excess acid in the blood or body tissues, resulting from the primary illness. Because carbon dioxide, mixed with water in the bloodstream, can add to the blood's acidity, lowering the level of carbon dioxide helps to compensate for the other acids.

Similarly, in an otherwise healthy person, tachypnea without physiologic demand for increased oxygen causes **respiratory alkalosis**, or a buildup of excess base (lack of acids) in the body fluids. The shift in the acid-base balance moves toward the base end of the scale.

Alkalosis is the cause of many of the symptoms associated with **hyperventilation syndrome (panic attack)**, including anxiety, dizziness, numbness,

tingling of the hands and feet (which can progress to actual spasms of the phalanges known as **carpopedal spasm**, in which the hands and feet become clenched into a clawlike position), and even a sense of dyspnea despite the rapid breathing. Although hyperventilation can be the body's response to illness and a buildup of acids, hyperventilation syndrome is not the same thing. Instead, this syndrome occurs in the absence of other physical problems. It commonly occurs when a person is experiencing psychological stress. The respirations of a person who is experiencing hyperventilation syndrome may be as high as 40 shallow breaths/min or as low as only 20 very deep breaths/min.

Causes of Dyspnea

Dyspnea is shortness of breath or difficulty breathing. Many different medical problems may cause dyspnea. Be aware that if the problem is severe and the brain is deprived of oxygen, the patient may not be alert enough to report shortness of breath. More commonly, altered mental status is a sign of hypoxia of the brain.

In addition to the conditions listed in Table 17-3, patients with the following medical conditions often experience breathing difficulty or hypoxia:

- Pulmonary edema
- Hay fever
- Pleural effusion
- Obstruction of the airway
- Rib fractures (flail segment)
- **Cystic fibrosis**
- Hyperventilation syndrome
- Prolonged seizures
- Neuromuscular disease (such as multiple sclerosis or muscular dystrophy)
- Environmental or industrial exposure to toxic gases
- Carbon monoxide poisoning
- Drug overdose

As you treat patients with disorders of the lung, you should be aware that one or more of the following situations most likely exists:

- Gas exchange between the alveoli and pulmonary circulation is obstructed by fluid in the lung, infection, or collapsed alveoli (**atelectasis**).
- The alveoli are damaged and cannot transport gases properly across their own walls.

- The air passages are obstructed by muscle spasm, mucus, or weakened airway walls.
- Blood flow to the lungs is obstructed by blood clots.
- The pleural space is filled with air or excess fluid, so the lungs cannot properly expand.

All of these conditions prevent the proper exchange of oxygen and carbon dioxide. In addition, the pulmonary blood vessels themselves may have abnormalities that interfere with blood flow and thus with the transfer of gases.

Besides shortness of breath, a patient with dyspnea may also report the sensation of chest tightness and air hunger. Air hunger is when a person reports the feeling of “not getting enough air” and has a strong need to breathe. Chest tightness is described as an uncomfortable feeling in the chest, and it is commonly reported by patients with asthma.

Dyspnea is also a common complaint in patients with cardiopulmonary diseases. In some cases, it may be caused by physical exertion that has been made difficult because the patient’s heart is damaged. Heart failure is a troublesome cause of breathlessness because the heart is not pumping efficiently and, therefore, the body does not have adequate oxygen. Another condition commonly associated with heart failure is pulmonary edema, in which the alveoli are filled with fluid.

Severe pain can cause a patient to experience rapid, shallow breathing without the presence of a primary pulmonary dysfunction. In some patients, breathing deeply causes pain because it causes expansion of the chest wall.

When you assess your patient for complaints of dyspnea, ask about chest pain; conversely, when you are evaluating your patient for chest pain, ask about dyspnea.

Words of Wisdom

Never withhold oxygen from any patient exhibiting signs of distress. If a patient with COPD stops breathing spontaneously (rare) as a result of increased levels of oxygen, it is a simple matter to coach breathing or to ventilate the patient and continue oxygenating organs and tissues. Withholding oxygen may result in an insufficient amount of inspired oxygen, and because of the decreased rate, depth, or other obstructive problem, vital organ damage may occur.

Upper or Lower Airway Infection

Infectious diseases causing dyspnea may affect all parts of the airway. Some cause mild discomfort; others require aggressive respiratory support. Infections that impair airflow through the airways are problems of respiration. Inadequate oxygen delivery to the tissues is a problem of oxygenation. Infections may cause dyspnea by obstructing airflow in the larger airways as a result of the production of mucus and secretions (colds, diphtheria) or by causing swelling of soft tissues located in the larger, upper airways (epiglottitis, croup). Infections may also impair exchange of gases between the alveoli and the capillaries (pneumonia). **TABLE 17-5** shows infectious diseases that are associated with some degree of dyspnea.

TABLE 17-5 Infectious Diseases Associated With Dyspnea

Disease	Characteristics
Bronchitis	• An acute or chronic inflammation of the lung that may damage lung tissue, usually associated with cough, production of sputum, and, depending on its cause, sometimes fever • Fluid also accumulates in the surrounding normal lung tissue, separating the alveoli from their capillaries. (Sometimes, fluid can also accumulate in the pleural space.) • The lung’s ability to exchange oxygen and carbon dioxide is impaired. • The breathing pattern in bronchitis does not indicate major airway obstruction, but the patient may experience tachypnea, an increase in the breathing rate, which is an attempt to compensate for the reduced amount of normal lung tissue and for the buildup of fluid.

Disease	Characteristics
Common cold	- A viral infection usually associated with swollen nasal mucous membranes and the production of fluid from the sinuses and nose - Dyspnea is not severe; patients complain of “stuffiness” or difficulty breathing through the nose.
Coronavirus disease 2019 (COVID-19)	- A contagious viral respiratory infection that is easily transmissible from person to person - Symptoms may mimic common cold and flu symptoms, including fever or chills, cough, shortness of breath or difficulty breathing, fatigue, muscle or body aches, headache, new loss of taste or smell, sore throat, congestion or runny nose, nausea or vomiting, and diarrhea. - Signs that indicate the need for emergency medical care include trouble breathing, persistent pain or pressure in the chest, new confusion, and inability to wake or stay awake.
Croup	- Inflammation and swelling of the whole airway (pharynx, larynx, and trachea) typically seen in children between ages 6 months and 3 years (FIGURE 17-6) - The common signs of croup are stridor and a seal-bark cough, which signal a substantial narrowing of the air passage of the larynx that may progress to marked obstruction. - Croup often responds well to the administration of humidified oxygen. - Croup is rarely seen in adults because the airways are larger.
Diphtheria	- Although well controlled during the past decade, it is still highly contagious and serious when it occurs. - The disease causes the formation of a diphtheritic membrane lining the pharynx that is composed of debris, inflammatory cells, and mucus. This membrane can rapidly and severely obstruct the passage of air into the larynx.
Epiglottitis	- Inflammation of the epiglottis due to a bacterial infection that can produce severe swelling of the flap over the larynx. Severe, rapidly progressive infection of the epiglottis and surrounding tissue that may be fatal because of sudden respiratory obstruction. - In preschool and school-age children (ages 4 to 7 years) especially, the epiglottis can swell to two or three times its normal size. - The airway may become almost completely obstructed, sometimes quite suddenly (FIGURE 17-7). - Stridor (harsh, high-pitched, continued, rough, barking inspiratory sounds) may be heard late in the development of airway obstruction. - Acute epiglottitis in the adult is characterized by a severe sore throat. - Less common in children than it was 20 years ago because of a vaccine that can help to prevent most cases
Influenza type A	- A virus that has crossed the animal/human barrier and has infected humans - Flu that has the potential to spread at a pandemic level
Meningococcal meningitis	- An inflammation of the meningeal coverings of the brain and spinal cord that can be highly contagious - The bacteria can be spread through the exchange of respiratory and throat secretions through coughing and sneezing. - The effects are lethal in some cases. Patients who survive can be left with brain damage, hearing loss, or learning disabilities. - Patients may present with flulike symptoms, but unique to meningitis are high fever, severe headache, photophobia (light sensitivity), and a stiff neck in adults. Patients sometimes have an altered level of consciousness and can have red blotches on the skin. - Use respiratory protection and report any potential cases.

(continues)

TABLE 17-5 Infectious Diseases Associated With Dyspnea (*continued*)

Disease	Characteristics
Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)	• A bacterium that can cause infections in different parts of the body • Transmitted by different routes, including the respiratory route; can enter the body through nonintact skin or respiratory droplets when patients cough • Difficult to treat because it is resistant to many commonly used antibiotics, especially methicillin • Most common in people with weakened immune systems, including those in hospitals and nursing homes
Pertussis (whooping cough)	• An airborne bacterial infection that affects mostly children younger than 6 years • Patient will be feverish and exhibit a “whoop” sound on inspiration after a coughing attack. • Highly contagious through droplet infection • Coughing spells can last for more than a minute; child may turn red or purple. • Does not cause the typical whooping illness in adults; causes severe upper respiratory infection that could be an entry pathway to pneumonia in older persons
Pneumonia	• An acute bacterial or viral infection of the lung that damages lung tissue, usually associated with fever, cough, and production of sputum • Fluid also accumulates in the surrounding normal lung tissue, separating the alveoli from their capillaries. (Sometimes fluid can also accumulate in the pleural space.) • The lung’s ability to exchange oxygen and carbon dioxide is impaired. • The breathing pattern does not indicate major airway obstruction, but the patient may experience tachypnea, an increase in the breathing rate, which is an attempt to compensate for the reduced amount of normal lung tissue and for the buildup of fluid.
Respiratory syncytial virus	• A major cause of illness in young children • Causes an infection of the lungs and breathing passages • Can result in other serious illnesses that affect the lungs or heart, such as bronchiolitis and pneumonia • Highly contagious and spread through droplets • Survives on surfaces, including hands and clothing • Look for signs of dehydration. • Humidified oxygen is helpful, if available.
Severe acute respiratory syndrome (SARS I)	• A virus that has caused substantial concern • A serious, potentially life-threatening viral infection caused by a recently discovered family of viruses best known as the second most common cause of the common cold • Usually starts with flulike symptoms, which may progress to pneumonia, respiratory failure, and, in some cases, death • Thought to be transmitted primarily by close person-to-person contact
Tuberculosis	• A disease that can lay dormant in a person’s lungs for decades, then reactivate • Dangerous because many tuberculosis strains are resistant to many antibiotics • Spread by cough; droplet nuclei can remain intact for decades. • Use a high-efficiency particulate air (HEPA) respirator.

FIGURE 17-6 Croup swells the lining of the larynx, which is the narrowest point in the child's airway.

Acute Pulmonary Edema

Pulmonary edema is an accumulation of fluid in the lungs and has various causes. The fluid accumulation causes a decrease in gas exchange and results in severe dyspnea. Severe myocardial damage caused by an acute problem (such as acute myocardial infarction) or a chronic problem (such as cardiomyopathy) results in reduced contractile force of the myocardium. In these cases, the left side of the heart cannot remove blood from the

FIGURE 17-8 In pulmonary edema, fluid fills the alveoli and separates the capillaries from the alveolar wall, interfering with the exchange of oxygen and carbon dioxide.

© Jones & Bartlett Learning.

lungs as fast as the right side delivers it. As a result, fluid backs up into the alveoli and in the lung tissue between the alveoli and the pulmonary capillaries. By physically separating the alveoli from the pulmonary capillary vessels, the edema interferes with the exchange of carbon dioxide and oxygen (**FIGURE 17-8**). There is not enough room left in the lung for slow, deep breaths.

Pulmonary edema can develop quickly, especially following a major cardiovascular insult. The patient usually experiences dyspnea with rapid, shallow respirations. In the most severe instances, you will see frothy pink sputum at the nose and mouth.

Not all patients with pulmonary edema have heart disease. Poisonings from inhaling large amounts of smoke or toxic chemical fumes can produce pulmonary edema, as can traumatic injuries of the chest and exposure to high altitudes. In these cases, fluid collects in the alveoli and lung tissue in

response to damage of the tissues of the lung or the bronchi.

Regardless of the initial cause, the resulting assessment findings are similar. Patients with pulmonary edema that is cardiogenic in origin may present with signs and symptoms of a cardiac emergency. Patients with noncardiogenic pulmonary edema tend to have a history of associated factors such as a hypoxic episode, shock, chest trauma, recent acute inhalation of toxic gases or particles, or recent ascent to a high altitude without acclimatizing. In both cases, patients may also present with dyspnea, **orthopnea** (severe dyspnea experienced when lying down or in a position that is not upright, and relieved by sitting or standing up), fatigue, reduced exercise capacity, and pulmonary **crackles** (formerly known as rales).

Words of Wisdom

Any nontrauma patient who is experiencing difficulty breathing should immediately be placed in a position of comfort.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a common lung condition that is a slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction. COPD is an umbrella term used to describe a few lung diseases including emphysema and **chronic bronchitis**.

COPD may be a result of direct lung and airway damage from repeated infections or inhalation of toxic gases and particles, but most often it results from cigarette smoking. Obstruction occurs in the bronchioles. The cilia are unable to remove excess mucus, creating a buildup. The bronchioles dilate naturally on inspiration, enabling air to enter the alveoli despite the presence of obstruction. The bronchioles naturally constrict on expiration, and air becomes trapped distal to the obstruction on exhalation.

Tobacco smoke is a bronchial irritant and can create chronic bronchitis, an ongoing irritation of the trachea and bronchi. Chronic bronchitis results from overgrowth of the airway mucous glands and excess secretion of mucus, which blocks the airway.

YOU are the Provider

Part 2

You find the patient sitting on the bed in a tripod position. She has cyanosis around her lips and is in obvious respiratory distress. She is slow to respond to questions and is unable to answer in complete sentences. Her pulse oximetry (SpO₂) is 91%. On auscultation of her chest, you note wheezing in the upper lobes and diminished breath sounds in the lower lobes. Her skin is warm and dry to the touch and she has strong, rapid radial pulses. Your partner places her on a nonrebreathing mask at 15 L/min and begins to take vital signs while you complete your assessment. A quick check shows no signs of peripheral edema. The patient states she has not felt well for a couple of days and she was discharged from the hospital about 1 month ago for exacerbation of her emphysema. Your partner relays her vital signs and you note that she is tachycardic and tachypneic. You advise the patient of your findings and recommendations and she consents to treatment and transport.

Recording Time: 1 Minute

Appearance	Pale, cyanotic, and anxious
Level of consciousness	Alert, lethargic, but slow to respond to questions due to dyspnea
Airway	Patent
Breathing	30 breaths/min
Circulation	Bounding radial pulses; skin is warm, pale, and cyanotic

- What would your next course of action be?
- Should this patient be loaded on the stretcher and treated in the ambulance, or should you treat her at the scene?

Patients have a chronic productive cough. The clinical definition of chronic bronchitis is a productive cough for at least 3 months per year for 2 or more consecutive years.³

Pneumonia develops easily when the passages are persistently obstructed. Ultimately, repeated episodes of irritation and pneumonia cause scarring in the lung and some dilation of the obstructed alveoli, resulting in COPD (**FIGURE 17-9**).

The most common form of COPD is emphysema. Emphysema is a degenerative condition characterized by destruction of the alveolar walls related to the destruction of pulmonary surfactant. Surfactant is a substance that lines and lubricates the alveolar walls, allowing them to easily expand and recoil. After the amount of surfactant is reduced, elasticity is diminished. With emphysema, elastic material in the lungs is lost when the alveolar air spaces are chronically stretched as a result of inflamed airways and obstruction of airflow out of the lungs. Normally, the lungs act like spongy balloons that are inflated; after they are inflated, they will naturally recoil because of their elastic nature, expelling gas rapidly. However, when they are constantly obstructed or when the elasticity is diminished, air is no longer expelled rapidly, and the walls

of the alveoli eventually fall apart, leaving large “holes” in the lung that resemble large air pockets or cavities.

Emphysema is an irreversible condition; however, with proper treatment, its progression can be slowed. Emphysema also makes the alveoli susceptible to collapse (atelectasis). Chronically low oxygen levels associated with emphysema stimulate the production of red blood cells, sometimes in excessive quantity (polycythemia). As a result, the patient’s skin tends to remain its normal color.

Most patients with COPD have elements of both chronic bronchitis and emphysema. They have a history of recurring lung problems and are almost always long-term cigarette smokers. Some patients will have more elements of one condition than the other; few patients will have only emphysema or bronchitis. Therefore, most patients with COPD will

Words of Wisdom

Normal breathing should be quiet and not grossly evident to you. If you can see or hear the patient breathe, there is a problem.

FIGURE 17-9 Repeated episodes of irritation and inflammation in the alveoli result in the obstruction, scarring, and some dilation of the alveolar sac characteristic of chronic obstructive pulmonary disease. **A.** Normal alveolus. **B.** Infection produces mucus and swelling. **C.** A mucus plug creates an obstruction and further dilation of the alveolus.

FIGURE 17-10 Typically, a patient with chronic obstructive pulmonary disease has a barrel-shaped chest and uses accessory muscles and pursed lips for breathing. Notice also that the patient is sitting in the tripod position.

© American Academy of Orthopaedic Surgeons.

produce sputum, have a chronic cough, and have difficulty expelling air from their lungs, with long expiration phases and wheezing.

The patient in an acute COPD episode will complain of shortness of breath with gradually increasing symptoms over a period of days and often exhales through pursed lips. Patients with COPD may complain of tightness in the chest and constant fatigue. Because air has been gradually and continuously trapped in their lungs in increasing amounts, their chests often have a barrel-like appearance (**FIGURE 17-10**). If you listen to the chest with a stethoscope, you will hear abnormal breath sounds, discussed in detail later in this chapter.

Asthma

Asthma is an acute spasm of the smaller air passages called bronchioles that is associated with excessive mucus production and spasm of the bronchiolar muscles (**FIGURE 17-11**).⁴ It is a common but serious disease. Asthma is a reversible obstruction that is caused by a combination of smooth-muscle spasm (bronchospasm), mucus production, and edema. **Status asthmaticus** is a severe, prolonged asthmatic attack that cannot be resolved with conventional treatment. It can be sudden or progressive,

FIGURE 17-11 Asthma is an acute spasm of the bronchioles. **A.** Cross section of a normal bronchiole. **B.** The bronchiole in spasm; a mucus plug has formed and partially obstructed the bronchiole.

© Jones & Bartlett Learning.

and those with slow onset tend to be more at risk of death. It is a dire medical emergency.

Asthma produces a characteristic wheezing as the patient attempts to exhale through partially obstructed air passages; wheezing is indicative of a narrowed lower airway. These same air passages open easily during inspiration so that breathing appears relatively normal; the wheezing is heard only when they exhale. This wheezing may be so loud that you can hear it without a stethoscope, which is known as audible wheezing. Continuous wheezing occurs during inspiration and expiration and is generally diffuse, or heard throughout the lungs, not just over one particular lobe. In other cases, the airways are so blocked that no air movement is heard (a silent chest). In severe cases, the actual work of exhaling is very tiring, and cyanosis, respiratory arrest, or both may develop.

Asthma affects people of all ages and is usually the result of an allergic reaction to an inhaled, ingested, or injected substance. It may also be induced by exercise, severe emotional stress, or respiratory infections.

Most patients with asthma are familiar with their symptoms and know when an attack is imminent. Typically, they will have appropriate medication with them or at home. Listen carefully to what patients tell you; they often know exactly what they need.

Anaphylactic Reactions

Patients who do not have asthma may still have severe allergic reactions. Anaphylaxis is a severe allergic reaction characterized by airway swelling and

dilation of blood vessels all over the body, which may substantially lower blood pressure. This condition is sometimes referred to as anaphylactic shock. Anaphylactic shock may cause respiratory distress that is severe enough to result in coma and death. The pathophysiology of anaphylaxis is covered in detail in Chapter 22, *Immunologic Emergencies*.

Anaphylaxis may be associated with widespread hives (urticaria), itching, signs of shock, and signs and symptoms similar to those of asthma. The airway may swell so much that breathing problems can progress from extreme difficulty in breathing to total airway obstruction in a matter of a few minutes. Most anaphylactic reactions occur within 30 minutes of exposure to the **allergen**, which can be anything from certain nuts or other foods to a penicillin injection. Because this may be the first time such a reaction to the substance has occurred, some patients may not know what caused the swelling and allergic reaction. In other cases, the patient may know of the allergen but not be aware of exposure. This is a true emergency.

Spontaneous Pneumothorax

Normally, the vacuum pressure in the pleural space keeps the lung inflated. When the surface of the lung is disrupted, however, air escapes into the pleural cavity, and the negative vacuum pressure is lost; the natural elasticity of the lung tissue causes the lung to collapse. The accumulation of air in the pleural space, which may be partial or complete, is called a pneumothorax (**FIGURE 17-12**). Pneumothorax is most often caused by trauma, but it also can be caused by some medical conditions without any injury. In these cases, the condition is called spontaneous pneumothorax.

Spontaneous pneumothorax may occur in patients with certain chronic lung infections or in young people born with weak areas of the lung. Patients with emphysema and asthma are at high risk for spontaneous pneumothorax when a weakened portion of lung ruptures, often during severe coughing. Tall, thin, athletic males are also at higher risk for spontaneous pneumothorax, particularly while performing strenuous activities, such as heavy lifting.

A patient with a spontaneous pneumothorax becomes acutely dyspneic (short of breath) and typically complains of **pleuritic chest pain**, a sharp,

FIGURE 17-12 A pneumothorax occurs when air leaks into the pleural space from an opening in the chest wall or the surface of the lung. The lung collapses as air fills the pleural space and the two pleural surfaces are no longer in contact.

© Jones & Bartlett Learning.

stabbing pain on one side that is worse during breathing or with certain movement of the chest wall. Patients may also present with subcutaneous emphysema, or air bubbles trapped under the skin in the subcutaneous tissue, that may be found while palpating the chest. By listening to the chest with a stethoscope, you may note that breath sounds are absent or decreased on the affected side. However, altered breath sounds are difficult to detect in patients with severe emphysema. Spontaneous pneumothorax may be the cause of a sudden worsening of dyspnea in a patient with underlying emphysema. Patients experiencing minor problems may be pale, diaphoretic, and tachypneic. Severe findings include altered mental status, cyanosis, tachycardia, unilaterally decreased breath sounds, local hyperresonance to percussion, and subcutaneous emphysema. Tracheal deviation may be seen as a late sign. These patients require immediate care to survive.

Pleural Effusion

A pleural effusion is a collection of fluid outside the lung on one or both sides of the chest. By compressing one or both lungs, it causes dyspnea (**FIGURE 17-13**). This fluid may collect in large

FIGURE 17-13 With a pleural effusion, fluid may accumulate in large volumes on one or both sides, compressing the lungs and causing dyspnea.

© Jones & Bartlett Learning.

volumes in response to any irritation, infection, heart failure, or cancer. Although it can build up gradually over days or even weeks, patients often report that their dyspnea began suddenly. Pleural effusions should be considered a possibility in any patient with lung cancer and shortness of breath.

When you listen with a stethoscope to the chest of a patient with dyspnea resulting from pleural effusion, you will hear decreased breath sounds over the region of the chest where fluid has moved the lung away from the chest wall. These patients frequently feel better if they are sitting upright. Definitive care for the patient with a pleural effusion includes removing the fluid, a procedure that must be performed by a physician.

Pulmonary Embolism

An **embolus** is anything in the circulatory system that moves from its point of origin and travels to a distant site where it lodges, creating a perfusion disorder by obstructing subsequent blood flow in that area. Beyond the point of obstruction, circulation can be markedly decreased or completely cut off, causing deep vein stasis or stagnation of blood, which can result in a serious life-threatening

FIGURE 17-14 A pulmonary embolism is a blood clot from the vein that breaks off, circulates through the venous system, and moves through the right side of the heart into a pulmonary artery. Here, it can become lodged and substantially obstruct blood flow.

© Jones & Bartlett Learning.

condition. Emboli can be fragments of blood clots in an artery or vein that break off and travel through the bloodstream. They also can be foreign bodies that enter the circulation, such as a piece of the material from a catheter shear or a bubble of air.

A pulmonary embolism is a blood clot (thrombus) formed in a vein, usually in the legs or pelvis, that breaks off and circulates through the venous system. The large clot moves through the right side of the heart and into a pulmonary artery, where it becomes lodged, substantially decreasing or blocking blood flow (**FIGURE 17-14**). Although the lung is actively involved in inhalation and exhalation of air, no exchange of oxygen or carbon dioxide takes place in the areas of blocked blood flow because there is no effective circulation. The level of arterial carbon dioxide increases as a result of the ventilation-perfusion mismatch, and the oxygen level may decrease substantially, perhaps to a point at which cyanosis develops.

Pulmonary emboli may occur as a result of damage to the lining of vessels, causing platelet aggregation, a tendency for blood to clot unusually fast

(hypercoagulability), or, most often, slow blood flow in a lower extremity. Slow blood flow in the legs can occur when patients are bedridden, which can result in the collapse of veins. Patients whose legs are immobilized following a fracture or recent surgery are at risk for pulmonary emboli for days or weeks after the incident. Pregnancy, active cancer, previous pulmonary embolism, first-degree relative who has had a pulmonary embolism, and obesity are other risk factors. Additional risk factors include recent surgery, pregnancy, oral contraceptives, smoking, infection, cancer, sickle cell anemia, and prolonged inactivity; patients who are bedridden also are at risk. Pulmonary emboli occur less commonly in active, healthy people without other risk factors.

A pulmonary embolism is one of the two types of venous thromboembolism, the other being deep vein thrombosis. An estimated 900,000 Americans are affected by venous thromboembolism each year, 100,000 of whom die from this condition. Regarding pulmonary embolism, sudden death is the first symptom in approximately 25% of cases.⁵ Other signs and symptoms, when they occur, include the following:

- Dyspnea
- Tachycardia
- Tachypnea
- Varying degrees of hypoxia
- Cyanosis
- Acute chest pain
- Hemoptysis (coughing up blood)

When a patient has a possible pulmonary embolus, the chief complaint is usually a sudden onset of inspiratory chest pain, dyspnea, and nonproductive cough. Identifying possible risk factors may help to narrow the causes for the chief complaint. With a large enough embolus, complete, sudden obstruction of the output of blood flow from the right side of the heart can result in sudden death.

Obstruction of the Airway

As an AEMT, you should always be aware of the possibility that a patient with dyspnea may have a mechanical obstruction of the airway and be prepared to treat it quickly. In an unresponsive patient, the obstruction may be the result of vomitus or a foreign object (**FIGURE 17-15A**) or improper positioning of the head so that the tongue is blocking the airway (**FIGURE 17-15B**).

FIGURE 17-15 A. Foreign body obstruction occurs when an object, such as food, is lodged in the airway. **B.** Mechanical obstruction also occurs when the head is not properly positioned, causing the tongue to fall back into the throat.

© Jones & Bartlett Learning.

Always consider upper airway obstruction from a foreign body first in patients who were eating just before becoming short of breath.

Environmental/Industrial Exposure

Many accidental exposures that cause inhalation injury and dyspnea occur at industrial sites. Pesticides, cleaning solutions, chemicals, chlorine, and other gases can be accidentally released and inhaled by employees. Sometimes chemicals such as ammonia and chlorine bleach are mixed and create a hazardous by-product. Carbon monoxide is another toxic, odorless, highly poisonous gas

that is produced in industrial settings by vehicles, gasoline-powered tools, and heaters.

The type of damage from the substance depends in large part on the water solubility of the toxic gas. Highly water-soluble gases such as ammonia will react with the moist mucous membranes of the upper airway and cause swelling and irritation. If the substance gets in the patient's eyes, they will also burn and feel inflamed and irritated. Less water-soluble gases such as phosgene and nitrogen dioxide may get deep into the lower airway, where they may cause pulmonary edema up to 24 hours later.

Cystic Fibrosis

Cystic fibrosis (CF) is a genetic disorder that affects the lungs and digestive system. The disease is usually fatal, with most children not living past their teens; however, because of advances in treatment, the life expectancy for patients with CF becomes better each year. With aggressive management and careful monitoring, some patients may live well into their 40s.

CF is caused by a defective gene, which makes it difficult for chloride to move through cells. This causes unusually high sodium loss and abnormally thick mucus secretions. The secretions in the lungs cause breathing difficulties and provide an ideal growing medium for bacteria, leaving the patient highly susceptible to infection. Ultimately, the lung damage from the condition results in lung disease, the primary cause of death in affected persons.

In CF, the child's symptoms range from sinus congestion to wheezing and asthmalike complaints. The child may have a chronic cough that produces thick, heavy, discolored mucus. The child may also present with tachypnea, shortness of breath, barrel chest, clubbed fingers, and cyanosis. The thick mucus may also collect in the intestines. The child often has dyspnea; this generally results in the parents calling EMS. Treat the child with suction and oxygen using age-appropriate adjuncts. Keep a keen eye out for respiratory insufficiency, signs of a respiratory infection, and intestinal blockage.

CF often causes death in childhood because of chronic pneumonia secondary to the thick pathologic mucus in the airway. Adults with CF are predisposed to other medical conditions, including arthritis, osteoporosis, diabetes, and liver problems.

Age-Related Conditions

Bronchiolitis

Bronchiolitis is an inflammation of the small airways (bronchioles) in the lower respiratory tract as a result of viral infection. The most common source of this disease is respiratory syncytial virus (RSV), although a new virus, *Metapneumovirus*, has also been found to cause this illness. These viruses occur with highest frequency during the late fall and winter months,⁶ and they primarily affect infants and children younger than 2 years. Severity ranges from mild to moderate respiratory distress with hypoxia and respiratory failure.

The signs and symptoms of bronchiolitis can be difficult to distinguish from those of asthma, but note the child's age. Asthma is rare in children younger than 1 year; an infant with a first-time wheezing episode occurring in late fall or winter likely has bronchiolitis. Mild to moderate retractions, tachypnea, diffuse wheezing, diffuse crackles, and mild hypoxia are characteristic findings. As with asthma, a sleepy or obtunded patient or one with severe retractions, diminished breath sounds, or moderate to severe hypoxia (oxygen saturation <90%) is in danger of respiratory failure and requires immediate ventilatory support and transport.

Respiratory Syncytial Virus

As mentioned, RSV is a common cause of illness in young children. It causes an infection in the lungs and breathing passages and can result in other serious illnesses such as bronchiolitis and pneumonia, as well as serious heart and lung problems in premature infants and children who have depressed immune systems.

RSV is highly contagious and can be spread through droplets when the patient coughs or sneezes. The virus can also survive on surfaces, including hands and clothing. Therefore, the infection tends to spread rapidly through schools and in child care centers.

RSV can also cause severe upper respiratory infections and typical asthma symptoms in adults and geriatric patients.

Croup

Croup is caused by inflammation and swelling of the pharynx, larynx, and trachea. This disease is

often secondary to an acute viral infection of the upper respiratory tract and is typically seen in children between ages 6 months and 3 years. It is easily passed between children.

The disease starts with a cold, cough, and a low-grade fever that develop over 2 days. The hallmark signs of croup are stridor and a seal-bark cough, which signal a substantial narrowing of the air passage of the trachea that may progress to marked obstruction. Peak seasonal outbreaks of this disease occur in the late fall and during the winter.

Croup is rarely seen in adults because their breathing passages are larger and can accommodate the inflammation and mucus production without producing symptoms. The airways of adults are wider, and the supporting tissue is firmer than in children.

Croup often responds well to the administration of humidified oxygen.

Epiglottitis

Epiglottitis is a life-threatening inflammatory disease of the epiglottis, the small flap of tissue at the back of the throat that protects the larynx and trachea during swallowing. It is usually caused by a bacterial infection that produces severe swelling of the flap over the larynx. Although epiglottitis may be seen at any age, it is much more predominant in children. The development of a childhood vaccine against *Haemophilus influenzae* has dramatically decreased the incidence of this disease.

In preschool and school-age children especially, the epiglottis can swell to two to three times its normal size. This puts the airway at risk of complete obstruction. Patients with epiglottitis will look very sick. Epiglottitis usually has a sudden onset in an otherwise healthy child; children with this infection look ill, complain of a very sore throat, and have a high fever. They will usually be in the tripod position and drooling. Patients may also have stridor, high-pitched inspiratory sounds indicating partial airway obstruction.

Occasionally, the constellation of symptoms of epiglottitis can also appear in an adult or a geriatric patient, especially if the patient has other issues, such as diabetes, that affect the ability to fight off disease. In adults, epiglottitis, or supraglottitis, can be caused by different bacterial or viral organisms.

Acute epiglottitis in an adult or geriatric patient can be potentially life threatening and not recognized because it more commonly occurs in pediatric patients. Deterioration can occur quickly in adults with acute epiglottitis. You should be concerned if your patient is an adult presenting with stridor or any other sign of anatomic airway obstruction.

Pneumonia

Pneumonia is caused by an infection of the lung parenchyma, which is the tissue of the lung itself. It is the eighth leading cause of death in the United States and is not a single disease, but a group of specific infections.⁷ Young children are at risk for pneumonia because of their immature immune systems. Older adults are also at risk because of age-related weakening of the immune system.

Pneumonia presents as a localized infection in the lungs that may cause atelectasis, or alveolar collapse. If not treated promptly, the infection may become systemic, resulting in sepsis and septic shock. Typical findings with pneumonia include an acute onset of fever and chills, productive cough with purulent (thick) sputum, pleuritic chest pain, and excessive mucus causing pulmonary consolidation that may be detected by auscultation in the form of crackles or rhonchi.

Pertussis

Pertussis (whooping cough) is an airborne bacterial infection that primarily affects children younger than 6 years. It is highly contagious and is passed through droplet infection. In infants younger than 6 months, pertussis can be life threatening.

A patient with pertussis will be feverish and exhibit a “whoop” sound on inspiration after a coughing attack. Symptoms of pertussis are generally similar to those of colds, and you should look for signs of dehydration. The coughing spells can last for more than 1 minute, during which the child may turn red or purple. This may frighten the parents into calling 9-1-1.

Pertussis in adults does not cause the typical whooping illness that it does in infants and toddlers, but can cause severe coughing spells that can actually result in fracture of the ribs, and if the patient is already weak, pertussis can result in hospitalization.

Airway Obstruction

Always consider upper airway obstruction from a foreign body first when a young child becomes short of breath. This is especially true of crawling babies, who might have swallowed and choked on a small object. Inflammation of the tonsils may also partially occlude the airway, creating an obstruction. Dysfunction of a tracheostomy may also create an upper airway obstruction, especially if plugged with mucus or other secretions.

The obstruction may be in the lower airway, below the vocal cords. Trauma to the trachea may result in a crushing injury, fractured larynx, or edema that obstructs the lower airway. Obstruction may also be in the form of obstructive lung disease, mucus accumulation, or smooth-muscle spasm. Edema also may be present when a patient has been exposed to toxic chemicals or superheated air, as in a structural fire.

Heart Failure

Sometimes, the heart muscle is so injured after a heart attack or other illness that it cannot circulate blood properly. The heart is not able to maintain cardiac output that meets the needs of the body; thus the heart is failing as a pump. In these cases, the left side of the heart cannot remove blood from the lung as fast as the right side delivers it. As a result, fluid builds up within the alveoli and in the lung tissue between the alveoli and the pulmonary capillaries. This accumulation of fluid is referred to as pulmonary edema, and it is usually a result of heart failure.

Patient risk factors for heart failure include hypertension and a history of coronary artery disease and/or atrial fibrillation, a condition in which the atria no longer contract, but instead quiver.

In most cases, patients have a long-standing history of chronic heart failure that can be controlled with medication. However, an acute onset may occur if the patient stops taking the medication, eats food that is too salty, or has a stressful illness, a new heart attack, or an abnormal heart rhythm.

Signs and symptoms of heart failure include difficulty breathing with exertion because the heart cannot keep up with the body's need for oxygen. Patients may also report a sudden attack of respiratory distress that wakes them at night when they are in a reclining position. This is caused by

fluid accumulation in the lungs. Patients also report coughing, feeling suffocated, cold sweats, and tachycardia.

Wet Lungs Versus Dry Lungs and “Cardiac Asthma”

Confusion sometimes exists between the concepts *wet lungs* in pulmonary edema, caused most often by heart failure, and *dry lungs* in COPD. **TABLE 17-6** compares the differences between COPD and heart failure.

Suppose you are called to assist an 80-year-old man who has experienced shortness of breath for 45 minutes. Physical examination reveals that his pulse and respirations are elevated and you can see that he has pedal edema and jugular venous distention. His lung sound check reveals wheezing. He has a history of hypertension, heart failure, and myocardial infarction; however, he has no history of smoking.

Are patients with heart failure supposed to have crackles rather than wheezing? Breath sounds are extremely helpful but can also be confusing. In a case in which the alveoli are so full of fluid, bubbles (the condition that gives the sound of crackles) cannot form. The bronchi also become constricted, which produces wheezing. This patient is experiencing cardiac asthma, which is even more confusing because the patient has no history of asthma.

Patients with COPD wheeze because of bronchial constriction and present with shortness of breath. Their breathing becomes progressively worse, and they have the most trouble breathing on exertion. Patients with COPD have chronic coughing and thick sputum. They do not have jugular vein distention or dependent edema and are usually long-term smokers with a thin, barrel-chested appearance. Their medications would include home oxygen, bronchodilators, and corticosteroids.

You should suspect heart failure in this patient because of the patient's elevated blood pressure, pedal edema, and history of heart failure. Unlike a typical patient with COPD, he has no history of smoking and takes diuretics and medications to reduce preload.

Patients with COPD have a slower onset of symptoms because their disease is worsened by infection and other stressors. Patients with left-side heart failure experience a fluid overload in the lung, which develops quickly from a failing pump.

TABLE 17-6 Comparison of Chronic Obstructive Pulmonary Disease and Heart Failure

	Chronic Obstructive Pulmonary Disease	Heart Failure
Description	- A slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction - Usually in long-term smokers	- A disease of the heart characterized by shortness of breath, edema, and weakness - Patient may or may not smoke.
Pathophysiology	Emphysema: - Destruction of the airways distal to the bronchiole - Destruction of the pulmonary capillary bed - Decreased ability to oxygenate the blood - Lower cardiac output and hyperventilation - Development of muscle wasting and weight loss Chronic bronchitis: - Excessive mucus production with airway obstruction - Pulmonary capillary bed undamaged - Compensation by decreasing ventilation and increasing cardiac output - Poorly ventilated lungs, resulting in hypoxemia - Increased carbon dioxide retention	- Damaged ventricles and failure of heart as a pump - Attempt by heart to compensate with increased rate - Enlarged left ventricle - Backup of fluid into the body as the heart fails to pump adequately
Appearance	- Use of accessory muscles Emphysema: - Thin appearance with barrel chest "Puffing" (pursed lip) style of breathing - Tripod position Chronic bronchitis: - May be obese - Difficulty with expiration	- Abdominal distention - Dependent edema (sacral or pedal) - Tachycardia - Increased respiratory rate - Anxiety - Inability to lie flat - Ashen or cyanotic
Level of consciousness	Normal or altered	Normal or altered
Neck veins	- Flat - Distended when heart failure also present	Distended
Skin color	- In emphysema, its normal color - In chronic bronchitis, blue, often cyanotic	Blue
Lung condition	- In emphysema, dry - In chronic bronchitis, wet when heart failure also present	Wet
Breathing	- Shortness of breath (mostly on exertion) - Breathing worsens over time (progressive)	- Shortness of breath all the time - Sudden onset of shortness of breath with acute exacerbation
Breath sounds	Rhonchi, wheezing	Crackles, wheezing
Circulation	No dependent edema	Dependent edema
Cough	- In emphysema, little or none - In chronic bronchitis, frequent or chronic cough	Coughing may be present; increases when supine
Sputum	- In emphysema, no mucus - In chronic bronchitis, excessive, thick mucus	Pink, frothy sputum
Medications	Home oxygen, bronchodilators, and steroids help open the airways.	Diuretics and antihypertensives help promote cardiac function and reduce fluid loads on the heart.

As you try to discern between COPD and heart failure, do not assume that *all* COPD patients have wheezing and *all* heart failure patients have crackles; keep an open mind so that you do not miss important differences. The best advice is to treat the patient, not the breath sounds. In some cases, a patient with COPD may have air passages that are so constricted that you do not hear anything.

Special Populations

Normal aging processes alter the respiratory system and the ability to exchange oxygen and carbon dioxide. Geriatric patients are at an increased risk of pneumonia or a worsening of asthma or COPD if the airways have lost muscle mass or tone. Secretions might not be expelled from the airways, allowing pneumonia to develop. Provide adequate ventilation and oxygenation according to the patient's needs. Geriatric patients may need ventilatory support for conditions that, in younger adults, are easily accommodated by the respiratory system.

Geriatric patients may also have a decreased ability to generate heat during a fever. Even a low-grade fever in a geriatric patient may have a serious underlying cause. Fever may also result in confusion or an altered mental status.

Patient Assessment

Assessment of patients in respiratory distress should be conducted as a calm, systematic process. Patients in respiratory distress are usually quite anxious, and they may be some of the most ill and challenging patients you will encounter.

Scene Size-up

As always, first consider standard precautions and use of personal protective equipment (PPE). Follow local protocols for standard and situational requirements.

Safety

If the patient is suspected of having coronavirus disease 2019 (COVID-19), use additional protective equipment, including an N95 mask, goggles, gloves, and protective covering for clothing.

Pulmonary complaints may be associated with exposure to a wide variety of toxins, including carbon monoxide, toxic products of combustion, or environments that have deficient ambient oxygen (such as silos and enclosed storage spaces). It is critical to ensure a safe environment for all EMS personnel before making patient contact. If necessary, personnel with specialized training and equipment should remove the patient from a hazardous environment.

Safety

Scene safety is crucial in a toxic environment, but you will not always know in advance that you are entering a toxic environment. Stay alert for clues. If you enter a house for a patient who is not feeling well and you notice others with the same symptoms, suspect a toxic emergency. Remain alert for clues throughout the call; clues may not always be apparent when you first arrive.

After you have determined that the scene is safe, determine how many patients there are and whether you need additional or specialized resources. If there are multiple people with dyspnea, consider the possibility of an airborne hazardous material release.

If the nature of the illness is in question, ask why 9-1-1 was activated. By questioning the patient and family and/or bystanders, you should be able to determine the nature of the illness.

Primary Survey

The major focus of the primary survey is to recognize and treat life threats or potential life threats. A variety of pulmonary conditions pose a high risk for death. Recognition of life threats and the initiation of resuscitation take priority over performing a detailed assessment. Signs of life-threatening respiratory distress in adults, listed from most ominous to least severe, include the following:

- Altered mental status
- Severe cyanosis
- Absent or abnormal breath sounds
- Audible stridor
- Two- to three-word dyspnea
- Coughing

- Tachycardia of more than 130 beats/min
- Abdominal breathing
- Change in respiratory rate or rhythm
- Pallor and diaphoresis
- The presence of retractions and/or the use of the accessory muscles
- Tripod positioning

Special Populations

In children, foreign bodies such as pencil erasers, candy, and beans frequently obstruct a nostril. These items often sit in the nose for a day or two before the child presents with pain and a foul-smelling nasal discharge. Do not try to remove the obstruction yourself.

Note your general impression of the patient. A patient in substantial respiratory distress will want to sit up or may be in the tripod position.

Does the patient appear calm? Is the patient anxious or restless? Is the patient listless and tired? How severe is the patient's breathing complaint? This initial impression will help you decide whether the patient's condition is stable or unstable. Use the AVPU (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive) scale to check for responsiveness. If the patient is alert or responding to verbal stimuli, you know that the brain is still receiving oxygen. Ask the patient about the chief complaint. If the patient is responsive only to painful stimuli or unresponsive, the brain may not be oxygenating well and the potential for an airway or breathing problem is more likely. If there is no gag or cough reflex, you need to immediately assess the patient's airway status. Within seconds, you will be able to determine if there are any immediate threats to life.

To evaluate airway and breathing, begin with these questions: Is the airway open and clear? Is the patient breathing? Provide the appropriate oxygen therapy for a patient with spontaneous breathing, or immediately provide positive-pressure ventilations for one who is apneic. If ventilating, determine if ventilations are effective. Is there equal rise and fall of the chest, and is the heart rate decreasing appropriately?

If not, try to reposition the airway and insert an airway adjunct to keep the tongue from blocking the airway. Continue to monitor the airway for fluid,

secretions, and other problems as you move on to assess the adequacy of your patient's breathing. Refer to Chapter 11, *Airway Management*, for a review of airway management and ventilation techniques.

The next step in assessing breathing in a patient with a respiratory emergency is to assess breath sounds. Techniques for this assessment are described at the end of this section.

After assessing breath sounds, evaluate circulation. Assess the pulse rate, rhythm, and character. Tachycardia or bradycardia indicates the patient may not be getting enough oxygen. An increased pulse rate is the body's way of responding to respiratory distress and can be an indicator of shock. Tachycardia is also a normal response to pain, fear, excitement, and exertion.

Assess for the presence of shock and bleeding. Respiratory distress in a patient could be caused by an insufficient number of red blood cells to transport the oxygen. Assess capillary refill in infants and children. Capillary refill is not considered a reliable assessment tool in the adult patient. Also assess perfusion by evaluating skin color, temperature, and condition.

You should now be able to identify any life threats in your patient by the following signs or symptoms:

- Problems with airway, breathing, and circulation (ABCs)
- Poor initial general impression
- An altered mental status
- Potential hypoperfusion or shock
- Chest pain associated with low blood pressure
- Severe pain anywhere
- Excessive bleeding

If the patient's condition is unstable and there is a possible life threat, address the life threat and proceed with rapid transport. This means you will keep your scene time short, providing only life-saving interventions. Perform a secondary assessment en route to the hospital. If the patient's condition is stable and there are no life threats, you may decide to perform a thorough secondary assessment on scene, after obtaining the patient history.

Assessing Breath Sounds

Auscultating breath sounds, or lung sounds, is one of the most important vital signs for your patient in respiratory distress. Listen over the bare chest.

Trying to listen through clothing may give you inaccurate information. The diaphragm of the stethoscope must be in firm contact with the skin. If your patient is lying down, bring the patient to a sitting position when possible based on the patient's overall condition, which is a better position for assessing breath sounds.

You need to determine whether your patient's breath sounds are normal (**vesicular breath sounds** represent air moving in and out of the alveoli, and **bronchial breath sounds** represent air moving through the bronchi) or decreased, absent, or abnormal (adventitious breath sounds). With your stethoscope, check breath sounds on the right and left sides of the chest, and compare each side (**FIGURE 17-16**). When you are listening on the patient's back, place the stethoscope head between and below the scapulae, not over them, or your assessment will not be accurate.

Make sure that you listen for a full respiratory cycle so you can detect the adventitious sounds that may be heard at the end of the inspiratory or expiratory phase. When you are assessing for fluid collection, pay special attention to the lower lung fields. Start from the bottom up and determine at which level you start hearing clear breath sounds.

FIGURE 17-16 Stethoscope placement for auscultation of breath sounds.

© Jones & Bartlett Learning.

You want to hear clear flow of air in both lungs. Not hearing the flow of air is considered an absent lung sound. The lack of air movement in the lung is a substantial finding. Listen carefully and do not confuse absent breath sounds with clear breath sounds. **TABLE 17-7** provides examples of breath sounds, the diseases that may be associated with them, and important signs and symptoms.

Abnormal breath sounds may include crackles, which are sounds of air trying to pass through fluid in the alveoli. They are usually related to chronic scarring of small airways. It is a crackling or bubbling sound typically heard on inspiration. There

YOU are the Provider

Part 3

You and your partner assist the patient onto the stretcher in a position of comfort while continuing the oxygen via nonrebreathing mask. The patient is placed in the ambulance, and per your protocols, you elect to administer a nebulized breathing treatment consisting of 2.5 mg of albuterol sulfate mixed in 3 mL of normal saline. After completion of the treatment, the patient continues to report shortness of breath and you note that she is still tachycardic. You notify the receiving facility of the treatments administered and patient response as well as current status. Medical control denies orders for a second nebulized treatment of albuterol because of the patient's tachycardia.

Recording Time: 7 Minutes

Respirations	28 breaths/min, wheezes bilaterally
Pulse	Strong and regular, 148 beats/min
Skin	Warm, pale, and cyanotic
Blood pressure	148/92 mm Hg
Oxygen saturation (SpO₂)	91% on 100% oxygen
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- How can you explain the patient's elevated heart rate?
- With this patient's history of COPD, should you be concerned about the hypoxic drive?

TABLE 17-7 Signs, Symptoms, and Adventitious Breath Sounds Associated With Specific Respiratory Diseases

Breath Sounds	Disease	Signs and Symptoms
Wheezes	Asthma	Dyspnea
	COPD	Productive or nonproductive cough
	Heart failure/pulmonary edema	Dependent edema, pink frothy sputum
	Pneumonia	Fever, pleuritic chest pain
	Bronchitis	Clear or white sputum
	Anaphylaxis	Hives, facial swelling, stridor, nonproductive cough
Rhonchi	COPD	Productive cough
	Pneumonia	Fever, pleuritic chest pain
	Bronchitis	Clear or white sputum
Crackles	Heart failure/pulmonary edema	Dependent edema, pink frothy sputum
	Pneumonia	Fever, pleuritic chest pain
Stridor	Croup	Fever, barking cough
	Epiglottitis	Fever, sore throat, drooling
Decreased or absent breath sounds	Asthma	Nonproductive cough, dyspnea
	COPD	Productive cough
	Pneumonia	Fever, pleuritic chest pain
	Hemothorax	Shock, respiratory distress
	Pneumothorax	Dyspnea, pleuritic chest pain
	Atelectasis	Fever, decreased oxygen saturation

Abbreviation: COPD, chronic obstructive pulmonary disease
© Jones & Bartlett Learning.

are high-pitched sounds called fine crackles and low-pitched sounds called coarse crackles. These sounds are often a result of heart failure, pulmonary edema, or fluid in the lungs caused by heart failure.

Rhonchi are lower pitched sounds caused by secretions or mucus in the larger airway. The sound resembles rattling. This can be heard with infections such as pneumonia, bronchitis, or in cases of aspiration.

Stridor is a high-pitched sound heard on inspiration as air tries to pass through an obstruction in the upper airway. This sound indicates a partial obstruction of the trachea and is seen in patients with anatomic or foreign body airway obstruction.

Wheezing is a high-pitched whistling sound typically heard on expiration. It indicates constriction and/or inflammation in the bronchus. Wheezing is common in patients with asthma and sometimes in patients with COPD. Because of large emphysematous air pockets and diminished airflow, sounds of breathing are frequently difficult to hear and may be detected only high up on the posterior portion of the chest.

A **pleural friction rub** is a squeaking or grating sound that occurs when the pleural linings rub together. If this occurs, the pleural layers have lost their lubrication, most commonly because of pleural inflammation. This condition is usually associated with pain on inspiration. The sounds may be heard anytime the chest wall moves; therefore, they can be heard on inspiration, expiration, or both.

Finally, snoring sounds are indicative of a partial upper airway obstruction, usually in the oropharynx.

History Taking

After you form your general impression and have completed the primary survey, ask the patient to describe the problem to determine the chief complaint.

Questioning a Patient With Difficulty Breathing

With patients in respiratory distress, the SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral

intake, Events leading up to the illness or injury) can be obtained from the family or bystanders if they are present. Limit the questions to pertinent ones; a patient who is in respiratory distress does not need to be using any additional air to answer questions.

Be sure to ask the following questions about a patient in respiratory distress:

- What is the patient's general state of health?
- Has the patient had any childhood or adult diseases?
- Have there been any recent surgeries or hospitalizations?
- Have there been any traumatic injuries?
- Is there any dyspnea or chest pain?

If time allows, also ask about the patient's immunization history.

Because chronically ill patients live with their condition every day, when they call EMS, something has changed for the worse. Ask about previous episodes, medication allergies, and current medications. The patient's subjective description of the problem is an accurate indicator of the acuity of this episode if the disease is chronic. Start by asking the patient "What happened the last time you had an attack this bad?" or "What did the doctor do then?" The answer provides an extremely useful predictor of the current episode's course. If you do not know the diagnosis, try to learn whether the problem is related primarily to ventilation, diffusion, perfusion, or a combination. Any history of intubation is an accurate indicator of severe pulmonary disease and suggests that intubation by paramedics may be required again.

Find out what the patient has already done for the breathing problem. Pay close attention to the medications the patient is currently taking. Does the patient use a prescribed inhaler or a small-volume nebulizer? If so, when was it used last? How many doses have been taken? Are there any pulmonary medications, and if so, are they inhaled, oral, or parenteral? Consult medical control. Remember

to report the name of the medication, when the patient last took a puff, how many puffs were used at that time, and what the label states regarding dosage. If medical control permits, you may administer a bronchodilator via nebulizer, which is discussed later.

If the patient does not have a prescribed inhaler, continue with the history taking and secondary assessment. Despite use of the inhaler, the patient's condition may continue to worsen. You need to reassess breathing frequently and be prepared to assist ventilation in severe cases.

Also, find out whether the patient has any allergies or history of medication reactions.

Use the OPQRST-I mnemonic to determine the specifics of pain and obtain specific information about the breathing problem:

- When did the breathing problem begin (Onset)?
- What makes the breathing difficulty worse or better (Provocation or palliation)?
- How does the breathing feel (Quality)?
- Does the discomfort move (Radiation/region)?
- How much of a problem is the patient having (Severity)? On a scale of 1 to 10, with 10 being the worst pain or difficulty the patient has ever had, how bad is it?
- Is the problem continuous or intermittent? If it is intermittent, how frequently does it occur and long does it last (Timing)?
- What has been done to alleviate the problem prior to EMS arrival (Interventions)? Any medications taken?

Other questions to ask include:

- Does the patient have a cough? Is it productive or nonproductive? If it is productive, what color is the sputum? Any increased sputum production?
- Is there any hemoptysis? Wheezing? Fever? Chills?
- Has there been any exposure to smoke or does the patient have a history of smoking?

Words of Wisdom

The presence of corticosteroids or other steroids in the patient's daily medication regimen strongly suggests severe chronic disease.

Chronic Respiratory Conditions

Different respiratory complaints offer different clues and different challenges. Patients with chronic conditions may have long periods in which they are able to live relatively normal lives but then

sometimes experience acute worsening of their conditions. That is when you are called, and it is important for you to be able to determine your patient's baseline status—in other words, the patient's normal condition—and what is different this time that made the patient call you. For example, patients with COPD (emphysema and chronic bronchitis) do not cope well with pulmonary infections because the existing airway damage makes them unable to cough up the mucus or sputum produced by the infection. The chronic lower airway obstruction makes it difficult for the patient to breathe deeply enough to clear the lungs. Gradually, the arterial oxygen level falls, and the carbon dioxide level rises. If a new infection of the lung occurs in a patient with COPD, the arterial oxygen level may fall rapidly. In a few patients, the carbon dioxide level may become high enough to cause sleepiness. In these cases, patients require respiratory support and administration of supplemental oxygen.

Patients with COPD usually have a long history of dyspnea with a sudden increase in shortness of breath. There is rarely a history of chest pain. More often, they will remember having had a recent “chest cold” with fever and either an inability

to cough up mucus or a sudden increase in sputum. If the patient is able to cough up sputum, it will be thick and is often green or yellow. The blood pressure of patients with COPD is normal; however, the pulse is rapid and occasionally irregular. Pay particular attention to the respirations. They may be rapid, or they may be slow.

Patients with asthma may have different triggers, including allergens, cold, exercise, stress, infection, and noncompliance with medication. It is important to try to determine what may have triggered the attack so that it can be treated appropriately. For example, an asthma attack that occurred while your patient was jogging in the cold will probably not respond to antihistamines, whereas one brought on by a reaction to pollen might.

Patients with heart failure often walk a fine line between compensating for their diminished cardiac capacity and decompensating. Many take several medications, most often including diuretics (also known as water pills) and blood pressure medications. Your history taking should include obtaining a list of all their medications and paying special attention to the events leading up to the current problem.

Words of Wisdom

Dyspneic patients might resort to using—and sometimes misusing—over-the-counter medications in addition to their prescribed medications. The following is a list of over-the-counter medications that a patient may be using in conjunction with prescribed medications:

- Antihistamines dry secretions and should not be taken by people who have asthma. Antihistamines are a common ingredient in many over-the-counter cough and cold medications.
- Antitussives are used to suppress coughs. Because coughing helps clear secretions from the airways, suppressing a cough might not be helpful. Coughs can be annoying, particularly if they interrupt sleep. However, the need for comfort must be weighed against the need to rid the airway of excess secretions. Overuse of antitussives can cause sedation, reduce respiratory drive, and cause excessive plugging of the airway with secretions. Many over-the-counter cough syrups also contain antihistamines that can cause problems if not used appropriately.
- Bronchodilators are available in some over-the-counter preparations. They often produce a

nonspecific response, meaning that the medication may also have a substantial effect on the heart and blood vessels, particularly when taken in addition to prescription bronchodilators. The most common over-the-counter bronchodilators are simply attenuated (diluted) forms of epinephrine.

- Diuretics can be found in diet pills and caffeine-containing products, including many beverages. People are often told to drink plenty of fluids to maintain hydration, but overindulging in beverages that contain alcohol or caffeine has the opposite effect.
- Expectorants thin out pulmonary secretions so that they can be coughed up. Most common expectorants can be purchased over the counter. Many products combine expectorants with antitussives or antihistamines. These combinations are often at odds with each other. People with increased mucus production should avoid antihistamine products, taking only products that contain the expectorant guaifenesin.

Secondary Assessment

The secondary assessment is a more in-depth assessment of body systems, and it addresses the specific chief complaint, for example, difficult breathing (dyspnea) or shortness of breath. The secondary assessment includes a physical examination and taking vital signs.

Street Smarts

Always treat your patient, not diagnostic test results!

As always, you should only proceed to history taking and the secondary assessment after all life threats have been identified and treated during the primary survey. If you are busy treating airway or breathing problems, you may not have the opportunity to proceed to a physical examination prior to arriving at the emergency department. Never compromise the assessment and treatment of airway and breathing problems to conduct a physical examination.

Sometimes it is not possible to quickly and definitively determine what is causing your patient's respiratory distress. For example, a 20-year-old at a picnic who experiences rapid onset of difficult breathing and hives after being stung by a bee will likely have a different problem than an older woman in a nursing home who is on multiple medications and has a cough and increasing shortness of breath that developed over the past week. Keep an open mind, gather as complete a history as possible, and perform a secondary assessment.

Additional pieces to the assessment and treatment puzzle may be revealed during the physical examination. For example, you are treating a patient in acute respiratory distress who is breathing at a rate of 40 breaths/min and has audible wheezing. Given this information, you may be unsure as to whether the patient is in heart failure or is having an asthma attack. The secondary assessment may provide you with some clues, such as a consistently elevated blood pressure and swollen legs and feet (pedal edema) that would lead you in the direction of heart failure.

Conduct an in-depth assessment when a patient reports shortness of breath. In addition to the

signs of air hunger present in all patients with respiratory distress, such as tripod positioning, rapid breathing, and use of accessory muscles, restriction of the small lower airways in patients with asthma often causes wheezing. Patients may have a prolonged expiratory phase of breathing as they attempt to exhale trapped air from the lungs. In severe cases, you may not actually hear wheezing because of insufficient airflow. As your patient tires from the effort of breathing and oxygen levels decrease, the respiratory and heart rates may decrease, and your patient may seem to relax or fall asleep. A change in mental status is one of the early warning signs of respiratory inadequacy and indicates a lack of perfusion to the brain. This may manifest itself as confusion, lack of coordination, bizarre behavior, or even combativeness.

When you are performing a secondary assessment on the respiratory system, look for overall symmetry of the chest, adequate rise and fall of the chest, and evidence of retractions or accessory muscle use. Does the patient have increased work of breathing? Assess breath sounds, and do a physical assessment, if warranted.

What is the patient's respiratory status? The respiratory rate is not an accurate indicator of respiratory status unless it is extremely slow. However, respiratory trends are essential for evaluating chronically ill patients. A slowing respiratory rate in the face of an unimproved condition suggests physical exhaustion and impending respiratory failure. The patient's respiratory pattern should be noted; respiratory patterns are listed in **TABLE 17-8**.

As you perform your physical examination, look for signs of increased work of breathing. Are the patient's lips pursed? Do you see any accessory muscle use in the neck? Many smokers and people with chronic respiratory diseases cough up sputum every day (especially first thing in the morning), so determine if the color or amount of this sputum has changed (**TABLE 17-9**). Jugular venous distention may accompany right-side heart failure, which may be caused by severe pulmonary arterial obstruction. It is important to note whether the mucus is **purulent** (puslike).

A secondary assessment of the cardiovascular system, especially when there is associated chest pain, should include checking and comparing distal pulses, reassessing the skin condition, and being alert for bradycardia and tachycardia.

TABLE 17-8 Respiratory Patterns

- Eupnea (normal breathing pattern)
- Tachypnea (rapid respiratory rate)
- Cheyne-Stokes respirations (a rhythmic breathing pattern characterized by periods of rapid and slow respirations alternating with periods of apnea; commonly seen in patients with head injury)
- Central neurogenic hyperventilation (deep, rapid respirations commonly seen in patients with head injury)
- Kussmaul respirations (deep, rapid respirations accompanied by an acetone or fruity odor on the patient's breath; seen in patients with diabetic ketoacidosis)
- Ataxic (Biot) respirations (rapid, irregular respirations with periods of apnea)
- Apneustic respirations (impaired respirations with sustained inspiratory effort)
- Apnea (cessation of breathing)

TABLE 17-9 Classic Sputum Types

Type of Sputum	Causes
Frothy, sometimes with a pink tinge	Heart failure
Thick	Dehydration or antihistamine use
Purulent	Infectious process (because the pus contains dead white blood cells)
Yellow, green, brown	Older secretions in various stages of decomposition
Clear or white	Bronchitis
Blood-streaked	Tumor, tuberculosis, pulmonary edema, or trauma from coughing

© Jones & Bartlett Learning.

When you are examining the chest, are there any obvious signs of trauma? Any retractions? Is the chest symmetric? A barrel chest indicates the presence of longstanding COPD. Listen to breath sounds if not previously done. Examine the extremities for skin color, condition, and temperature. Numbness, tingling, and carpopedal spasm may be associated with hypocapnia resulting from periods of rapid, deep respiration.

Words of Wisdom

What is the patient's pulse rate? Tachycardia is a sign of hypoxemia or might be a result of sympathomimetic medications taken for respiratory difficulty. Bradycardia in a patient experiencing dyspnea is an ominous sign of severe hypoxemia and imminent cardiac arrest. What is the patient's blood pressure? Hypertension may be associated with the use of sympathomimetic medication.

Blood pressure should be auscultated (by listening) when possible to obtain the systolic and diastolic measurements. If you are in an environment where you cannot hear well enough to auscultate the blood pressure, then palpation (by feeling) is an alternative. It is preferable to auscultate when you can because palpation does not provide a diastolic value that may be pertinent when a patient has a condition such as hypertension.

When there is inadequate oxygen in the blood, the body will attempt to divert blood from the extremities to the core to help keep the vital organs, including the brain, perfused. This action will result in pale skin and delayed capillary refill in the hands and feet. Feel for the skin temperature, and look for color changes in the extremities and in the core of the body. Cyanosis is an ominous sign that requires immediate, aggressive intervention.

It is important to assess the neurologic system frequently because the level of consciousness can change. Check the patient's mental status and determine if the patient's activity can be described as anxious or restless. If so, that could be an indicator of hypoxia. Does the patient have clear thought processes? Disorientation may be another indicator of hypoxia.

Use monitoring devices if you have them available, including, but not limited to, a pulse oximeter. Under normal circumstances, a pulse oximeter is a noninvasive device that measures the percentage of a patient's hemoglobin that has oxygen attached to it. Oxygen saturation greater than 94% is considered normal, and most healthy people would feel short of breath at a saturation rate of less than 88%. Diagnostic testing will provide baseline information and indicate the severity of hypoxemia. Pulse oximetry is used to evaluate or confirm the adequacy of oxygen saturation.

Words of Wisdom

Most pulse oximeters also display the patient's pulse rate; this reading should match the patient's palpated heart rate. Always palpate the patient's pulse and compare it to the reading on the pulse oximeter.

Pulse oximetry readings may be inaccurate in the presence of conditions that abnormally bind hemoglobin, including carbon monoxide poisoning, as well as any condition that causes a decrease in perfusion. For example, if the patient's hemoglobin level is low (as a result of trauma or hemorrhage, for example), the pulse oximetry result will be correspondingly high. If the reading shows only 6 g/dL of hemoglobin (normal level, 12 to 14 g/dL), ideally all hemoglobin will have oxygen attached and the oxygen saturation will be 100%. Such a patient needs more hemoglobin in the form of whole blood or packed red cells. A patient with an abnormally high hemoglobin level, as is common in chronic hypoxia such as in cases of COPD, or a patient who lives at a high altitude will have a correspondingly low oxygen saturation.

Another more accurate tool available to AEMTs in some EMS systems is end-tidal carbon dioxide (ETCO₂) monitoring, which is a method for measuring the amount of exhaled carbon dioxide. ETCO₂ monitoring is accomplished with a device that measures the amount of carbon dioxide exhaled during a specific time (minutes or hours) and plots the resulting values graphically as a waveform as well as giving numeric readouts. ETCO₂ monitoring can be extremely valuable in assessing patients, but rarely results in different prehospital care for AEMTs.

The exact percentage of carbon dioxide contained in the last few milliliters of the patient's exhaled air can be measured using a special sensor. For example, some electronic ETCO₂ detectors use a photoelectric sensor that relies on absorption of infrared light by carbon dioxide to provide this measurement. The sensor can evaluate ETCO₂ in a spontaneously breathing patient via a specialized nasal cannula-type device, or it can be attached to the end of an endotracheal tube. These devices typically display a waveform that can provide additional data about the patient's respiratory status. In addition, such monitors serve as alarms that can

alert providers to changes in respiratory rate or depth. This kind of monitoring is called waveform capnography.

The recent realization that the amount of ETCO₂ in the exhaled breath of a patient in cardiac arrest is an important indicator of the effectiveness of cardiopulmonary resuscitation (CPR) has resulted in a substantially increased awareness of this important value. In cardiac arrest, an ETCO₂ of less than 10 torr (torr = mm Hg) may indicate suboptimal CPR compressions. A sudden increase in ETCO₂ (for example, from 10 to 35 mm Hg) may be the earliest indicator of the return of spontaneous circulation. Keep in mind that the ETCO₂ value can be dramatically affected by the rate and depth of ventilation. The ultimate value of this parameter depends on a provider's ability to maintain ventilation at recommended levels (8 to 10 breaths/min at 6 to 7 mL/kg in an adult in a state of cardiac arrest).

Assessment Pearls

- Protect yourself!! Use appropriate PPE for the given situation.
- Nonbreathing masks do not provide protection from airborne transmissions. Any patient with a suspected airborne illness needs to have a surgical mask placed underneath the nonbreathing mask.
- Adequate oxygenation has more to do with tidal volume than with the rate. Make sure your patient has good chest rise and fall.
- Not all wheezing is caused by asthma. Look for the underlying cause of the bronchoconstriction. The same is true of hyperventilation; look for the underlying cause.
- A decreasing heart rate is not always a good sign in a patient with respiratory distress. Instead, bradycardia may be a sign of exhaustion and impending respiratory failure.
- Add saline to the bowl of a **small-volume nebulizer** with a mask to provide humidified oxygen.
- For a child in respiratory distress, administer oxygen in such a way as to not agitate the child. Be creative! Run oxygen tubing through the bottom of a Styrofoam cup or underneath the "arm" of a stuffed animal held near the patient's face.
- IV fluid can be useful to thin out secretions, making it easier for the patient to clear the secretions by coughing. However, remember to auscultate breath sounds frequently when providing IV therapy.

Another tool is the peak flowmeter. This device provides a baseline assessment of expiratory airflow for patients with obstructive lung disease. The peak flow is the maximum flow rate at which a patient can expel air from the lungs. Normal peak flow values vary by age, sex, and height, but generally range from approximately 350 to 700 L/min; a peak flow less than 150 L/min is considered inadequate and signals substantial distress. Some people with chronic asthma have a peak flow that never exceeds 100 L/min. Many patients with chronic pulmonary diseases may already use a peak flowmeter at home. Encourage these patients to take their records and medications with them to the hospital for evaluation of the progression of their illness.

Reassessment

After the assessment and treatment have been completed, you need to reassess the patient and closely watch patients with shortness of breath. Repeat the primary survey and maintain an open airway. Monitor the patient's breathing and reassess circulation.

Determine if there have been changes in the patient's condition. Confirm the adequacy of interventions and patient status. If the changes you find are improvements, simply continue the treatments; however, if your patient's condition deteriorates, prepare to modify treatments. Be prepared to assist ventilations with a bag-mask device. Monitor the skin color and temperature. Reassess and record vital signs at least every 5 minutes for a patient in unstable condition and/or after the patient uses an inhaler. If the patient's condition is stable and no life threat exists, vital signs should be obtained at least every 15 minutes.

Contact medical control with any change in level of consciousness or difficulty breathing. Depending on local protocols, contact medical control prior to assisting with any prescribed medications. Be sure to document any changes (and at what time) and any orders given by medical control.

Emergency Medical Care

This section will discuss how to manage a patient with dyspnea. Later in the chapter, the management of specific diseases and conditions will be discussed.

Perform Standard Interventions

In treating a patient with dyspnea, a variety of standard interventions should be implemented before administering medication. Oxygen to keep the saturation above 94% and an intravenous (IV) line are typical interventions for any patient who needs advanced life support.⁸

Psychological support is also an important consideration for a patient with dyspnea. Always speak with assurance and assume a calm, professional, and caring demeanor to reassure the patient, who, no doubt, will be very frightened. Your efforts to reduce that patient's anxiety can help lower the patient's heart rate and blood pressure and allow the patient to maximize breathing effectiveness.

Decrease the Work of Breathing

Even under normal circumstances, muscles must work to allow breathing, and they must work much harder during respiratory distress. People with asthma, for example, can often compensate for respiratory distress by devoting substantial energy to breathing. They can maintain their oxygen and carbon dioxide levels in an acceptable range as long as they continue to recruit their muscles for this effort. The tremendous workload uses large amounts of energy, which requires even more oxygen and ventilation. A patient in such a condition typically is not able to eat and drink normally and becomes progressively more dehydrated, malnourished, and fatigued. At some point, the patient will tire and be unable to continue the necessary work of breathing; the patient will look sleepy, the rate and depth of respirations will slowly decrease, and the patient will experience decompensation (respiratory failure). Some patients with asthma may compensate for days, hoping that their steroids and bronchodilators will resolve an attack. By the time they realize that those approaches are not working, they may be in too much distress to seek care except by calling 9-1-1.

The supine position with or without the legs raised, especially for an overweight patient, causes the abdominal organs to compress the diaphragm. With each breath, the patient must move the abdominal contents out of the way to expand the thorax and breathe. Abdominal distention with air or blood compounds the situation. Shortness of breath induced by lying flat is called orthopnea. It

explains why most people maintain a sitting position when they are short of breath. To decrease the work of breathing, help the patient sit up if this position is more comfortable. Remove constricting clothing, such as belts and tight collars. *Do not make the person walk.*

Provide Supplemental Oxygen

It is essential to provide supplemental oxygen to any patient who needs it. As with any other medication, you must administer oxygen in the concentrations necessary to be effective. Patients who are not breathing adequately should receive bag-mask ventilation with supplemental oxygen, or more advanced airway management techniques. Closely reassess the patient's breathing status, and adjust treatment accordingly. Pulse oximetry is a useful guide to oxygenation if it is accurate (the pulse rate on the oximeter matches the palpated pulse) and if the patient's hemoglobin level is relatively normal.

It is safe to administer oxygen in concentrations less than 50% to almost anyone, and it is appropriate to do so when there is a reasonable chance the patient would benefit from it. Oxygen concentrations higher than 50% should be reserved for patients with hypoxia that does not respond to lower concentrations. The use of 100% oxygen should be limited to the shortest period necessary.

Of the oxygen in the body, 97% is bound to hemoglobin. The other 3% is dissolved in the plasma. After all hemoglobin in the blood has been saturated with oxygen, further exposure to high concentrations of oxygen begins to damage the lung tissue.

As an AEMT, you will treat many patients who require high-concentration oxygen to maintain acceptable oxygen saturation. You should never hesitate to administer oxygen aggressively to those patients who need it. At the same time, however, most patients with good oxygen saturation (at least 94%) do not benefit from supplemental oxygen.⁸⁻¹⁰ Even patients with trauma, stroke, and acute coronary syndrome derive no benefit from supplemental oxygen therapy if oxygen saturation is already at or above 94%.¹¹ It remains common practice to administer low-flow oxygen to such patients, but **hyperoxia** (an excess of oxygen) should be avoided. In general, the American Heart Association recommends maintaining oxygen saturation between 94% and 99%.¹¹ Oxygen saturation of 100%

should be avoided, because it's impossible to predict how high the blood oxygen level may rise when the hemoglobin is completely saturated.

Also, remember to consider the possibility that the pulse oximeter may provide falsely elevated assessment of the patient's overall level of oxygenation, such as in cases of carbon monoxide poisoning or anemia due to acute blood loss or chronic anemia. In such cases, providing supplemental oxygen sufficient to achieve an oxygen saturation of 100% may be extremely valuable. There is no evidence that short-term hyperoxia is detrimental to any group of patients. There is some evidence that long-term hyperoxia (several hours) may be associated with worse outcomes (acute coronary syndrome and traumatic brain injury). In the context of very prolonged transport times, these factors and conditions should be considered. In the context of very short transport times (less than an hour), there is essentially no danger to hyperoxia, and oxygen therapy should be employed liberally.

Always consider insertion of an advanced airway in unresponsive patients to protect the airway. Call for paramedic backup if needed.

Special Populations

In the 1950s, scientists began to understand that administering high concentrations of oxygen could cause blindness in premature neonates. Thus began the medical community's recognition that oxygen can have toxic effects. Current protocols now discourage the use of 100% oxygen in neonatal care, even during initial resuscitation (100% oxygen is still given, however, in neonatal cardiac arrest).¹² Further research is being done on the effects of free radicals and the effect of high-concentration oxygen on all patients.

Administer a Bronchodilator

Many patients with respiratory distress receive some benefit from bronchodilation, and some patients benefit substantially. Today's aerosol bronchodilators rarely harm patients, so AEMTs tend to use them aggressively in the field. However, patients who do not have bronchospasm usually benefit only slightly from aerosol bronchodilators, and the oxygen concentration delivered is often reduced

during a typical aerosol treatment. Under these circumstances, application of a nonrebreathing mask is a better choice than the aerosol treatment. Follow local protocol, but remember bronchodilators are of little value in treating conditions such as pneumonia, pulmonary edema, and heart disease.

Respiratory Medications

Some of the most common medications used for dyspnea are called inhaled beta agonists, which, through stimulation of selective beta-2 receptors in the lungs, dilate the bronchioles. Typical trade names are Proventil, Ventolin, Alupent, Metaprel, and Brethine. The generic name for Proventil and Ventolin is albuterol; for Alupent and Metaprel, it is metaproterenol; and for Brethine, it is terbutaline. The action of most of these medications is to relax the smooth muscles within the bronchioles in the lungs, resulting in enlargement (dilation) of the airways and easier passage of air.

Bronchodilators relax the smooth muscle around the larger bronchi and are an important therapy for bronchoconstriction. Administered via so-called rescue inhalers, fast-acting bronchodilators provide rapid relief, a property that

sometimes results in their misuse. Strictly speaking, bronchodilators do not reduce swelling, kill bacteria, push fluid out of the lungs, or open closed alveoli. However, patients with pneumonia, heart failure, or atelectasis may have a small amount of secondary bronchoconstriction that could be reversed with a bronchodilator.

In the past, the strategy was to disperse atropine (the most common parasympathetic blocker) through an aerosol. Currently, a medication specifically designed for aerosol use, ipratropium, is available. It is also available in a metered-dose inhaler (MDI). The combination of albuterol (a beta-2 agonist) and ipratropium (an anticholinergic) is also available as a so-called premixed cocktail, as an aerosol, or as an MDI.

Anticholinergics have emerged as a central component in the management of COPD. Tiotropium (Spiriva), a once-per-day anticholinergic for this indication, is taken via a type of dry-powder inhaler. Patients taking tiotropium would not typically also use aerosol ipratropium.

TABLE 17-10 lists medications used for acute and chronic respiratory symptoms. Those used for acute symptoms are designed to give the patient

TABLE 17-10 Respiratory Inhalation Medications							
Medication			Indications			Use

rapid relief from symptoms if the condition is reversible. Medications used for chronic symptoms are administered for preventive measures or as maintenance doses. The medications for chronic use will provide little relief of acute symptoms. Common side effects of inhalers used for acute shortness of breath include increased pulse rate, nervousness, and muscle tremors.

Some of these medications are administered in the home by using an aerosol nebulizer, an MDI, or a dry-powder inhaler.

FIGURE 17-17 Aerosol nebulizers are often used to deliver medications directly to the respiratory tract. Unfortunately, they may supply only 30% to 40% oxygen during a treatment. Flow rate is an important factor in how much medication reaches the lungs.

© Chas/Shutterstock.

Safety

During the COVID-19 pandemic, some agencies did not allow respiratory treatments via small-volume nebulizers in the back of the ambulance due to the confined space and risk of disease transmission.

Aerosol Therapy

An aerosol treatment is a simple method of delivering medications, such as bronchodilators. Aerosol nebulizers deliver liquid medications in the form of a fine mist (**FIGURE 17-17**). To generate the optimal particle size, most nebulizers need to have gas (oxygen) flow of at least 6 L/min. Running the

gas more slowly generates particles that are too large and cannot make it into the lower airways; running it substantially faster makes the treatment go faster, with the potential of less medication delivery.

In the home, most people run their aerosol treatments off of a small air compressor. In the ambulance, this therapy usually runs off of tanked

oxygen or a wall unit attached to the main oxygen supply. As a result, the patient might receive only 30% to 40% oxygen via an aerosol treatment, which is still more than the 21% oxygen contained in room air but may be less than needed by a patient with substantial hypoxia.

A nebulizer can be attached to a mouthpiece (pipe), a face mask, or a tracheostomy collar, or it can simply be held in front of the patient's face (called the blow-by technique). The smaller the amount of mist the patient inhales, however, the less medication the patient receives. Blow-by and mouthpiece treatments are ineffective if patients continually turn their heads or remove the mouthpiece to answer questions. As such, after the decision has been made to deliver a breathing treatment, try to stop the conversation and let the patient focus on inhaling the medication.

Controversies

In some systems, aerosol treatments are given to anyone who is dyspneic under the belief that they might help and are usually harmless; in other systems, the use of aerosol bronchodilators is restricted to situations in which they are clearly indicated. Be sure to consult medical direction and your local protocols to keep abreast of how this class of medications is used in your region.

Nebulizers also deliver substantial humidity to the airway. A quick way to provide a cooling mist to the swollen upper airway of a patient with burns or a child with croup is to give an aerosol treatment of saline solution or sterile water.

The newer aerosol bronchodilators cause far less tachycardia than those that are older and less beta-2-specific. As a result, it has become possible to give repeated treatments to patients with bronchospasm. Continuous nebulizers are available that hold up to 10 times the usual medication dosages and run for 1 hour or longer. However, the potential for some beta-1 stimulation (causing tachycardia) remains, and some physicians are concerned that aerosol bronchodilators could worsen tachycardia in a patient with underlying cardiac disease. Tachycardia is almost always already present in patients with dyspnea, so be sure to consult medical control or local protocols for guidance. The steps for

Words of Wisdom

Albuterol is one of the most commonly administered bronchodilators given via nebulizer and can be administered by AEMTs. Dosages are as follows:

- **Adult:** Administer 2.5 mg diluted with 2.5 mL of normal saline.
- **Pediatric:** Administer as follows:
 - Patients who weigh less than 20 kg: 1.25 mg/dose via handheld nebulizer or mask over 20 minutes.
 - Patients who weigh more than 20 kg: 2.5 mg/dose via handheld nebulizer or mask over 20 minutes.
 - Repeat once in 20 minutes; consult medical control regarding the second dose, depending on local protocols.

administering medications via small-volume nebulizer are shown in Chapter 13, *Vascular Access and Medication Administration*.

Metered-Dose Inhalers

An MDI is a miniature spray canister used to direct medication through the mouth and into the lungs. When properly used, an MDI should deliver the same amount of medication as an aerosol treatment. This device is small, easy for patients to carry and use, and convenient. Because it does not require additional equipment (such as a nebulizer or air compressor), it is usually the delivery method of choice for bronchodilators and corticosteroids in the home setting (**FIGURE 17-18**). Because patients

FIGURE 17-18 Metered-dose inhalers are a common delivery platform for respiratory medications. Their effectiveness is greatly increased by using a spacer device (shown here), which regulates the release of medication from the inhaler.

© Jones & Bartlett Learning.

use (and may misuse) their own inhalers in the home, be sure to document how often the patient has been taking an extra puff. Do not forget to consult medical control before administering additional doses if this is required in your system.

Each MDI on the ambulance should ideally be equipped with a **spacer**. A spacer is a device that collects the medication as it is released from the canister, allowing more to be delivered to the lungs and less to be lost to the environment. When a spacer is used, the patient does not have to worry about timing the inhalation to coincide with the discharge of the inhaler. Spacers also reduce deposition of the drug into the mouth and oropharynx, which is a problem with inexperienced users.

Achieving the proper technique when using an MDI is not difficult, but it requires constant reinforcement. The steps for administering medication with an MDI are shown in Chapter 13, *Vascular Access and Medication Administration*.

The following are some tips on how to avoid common errors when using or administering an MDI:

- **The mist from an MDI must enter the lungs.** Patients must inhale deeply as they discharge the inhaler to draw the medication deep into their lungs. Placing the inhaler directly into the mouth (without a spacer) often causes much of the medication to fall on the posterior pharynx, where it is swallowed and digested, thus negating its intended effect.
- **Some patients mistakenly blow into the spacer.** Tell them to think of the spacer as a big straw from which they should try to suck the medication out of the bottom.
- **Many spacers make a harmonica-like sound if the patient sucks too hard.** The best particle deposition comes from smooth, low-pressure, laminar flow. Inhaling too forcefully causes turbulent flow, which makes many of the particles stick to the trachea and large bronchi, where they are not as effective.
- **Patients should try to inhale the medication deeply and then hold their breath for a few seconds.** This is a lot to ask of someone who is dyspneic, and it is not always possible. Sometimes the inhalation causes the patient to cough immediately after inhaling the medication, which precludes delivery of a full dose but may be unavoidable.

- **Make sure the inhaler contains medication.** The labels of most inhalers list the number of puffs of medication in the canister. Patients should be encouraged to keep track of how many times they have used the inhaler and to discard it when they reach the recommended number of uses. The sound of fluid sloshing around when the canister is shaken doesn't indicate that there is medication left in it.
- **Keep the spacer and canister holder clean.** The spacer and canister holder should occasionally be rinsed off to avoid inhaling dust and other particles. In addition, respiratory devices should be dried after they are cleaned to avoid the growth of microorganisms.
- **After using a corticosteroid inhaler, patients should rinse out the mouth with water or mouthwash.** Residual corticosteroid in the pharynx can predispose patients to thrush, an annoying fungal infection in the pharynx or mouth.

Special Populations

In asthma education programs, children learn to take a puff from a bronchodilator inhaler, turn over an hourglass egg timer, and wait 1 or 2 minutes before taking the next puff. This strategy lets the medication delivered in the first puff open the airways a little so the second puff can go deeper into the airways.

If a patient with shortness of breath has a prescribed MDI, read the label carefully to make sure that the medication has been prescribed to the patient and that it is not expired. The patient should take repeated doses of the medication if the maximum dose has not been exceeded and the patient is still experiencing shortness of breath. Contraindications for the use of an MDI include the following:

- The patient is unable to help coordinate inhalation with depression of the trigger on an MDI or is too confused to effectively administer medication through a small-volume nebulizer. These devices will be only minimally effective when patients are in respiratory failure and have only minimal air movement.
- The MDI or small-volume nebulizer is not prescribed for this patient.

- You did not obtain permission from medical control and/or it is not permissible by local protocol.
- The patient had already met the maximum prescribed dose before your arrival.
- The medication is expired.
- There are other contraindications specific to the medication.

Words of Wisdom

Positioning the patient in an upright position to loosen mucus and relieve buildup can be effective in treating a patient with a respiratory emergency.

You must carefully monitor patients with dyspnea. About 5 minutes after the patient uses an inhaler, repeat the vital signs and the primary survey. Ask the patient whether the treatment was effective. Look at the patient's chest to see whether the patient is still using accessory muscles to breathe. Listen to the patient's speech pattern. Be prepared to assist ventilations with a bag-mask device if the patient's condition deteriorates.

After helping the patient with the inhaler treatment or administering a bronchodilator via nebulizer, transport the patient to the closest, most

appropriate emergency department. While en route, continue to assess the patient's breathing. Provide reassurance and continue to give supplemental oxygen. In cases of severe distress, do not delay transport. Using MDIs as well as administering nebulized treatments may be done en route.

Dry-Powder Inhalers

Some respiratory medications are most stable in the form of a fine powder. Several common corticosteroids and slow-acting bronchodilators are often dispensed by this means. Each time the device is opened, the small plastic blister that holds a dose is rotated into position. The patient then pushes a small lever to puncture the blister, presses the disk to the lips over the opening, and inhales deeply to suck the powder out of the device. These devices are

Documentation and Communication

Teach patients to use their rescue inhalers before taking corticosteroids, slow-acting bronchodilators, and other medications. A rescue inhaler dilates the bronchi so that subsequent medications are more effective.

YOU are the Provider

Part 4

You auscultate the patient's lungs again, and although you still hear wheezing, you also note increased air movement, and the patient's cyanosis is resolving slightly. You place the patient back on a nonbreathing mask at 15 L/min and establish an IV line with a 20-gauge catheter in her left antecubital fossa with normal saline at a to-keep-open rate. The patient states that her breathing is much easier en route, but you note that she is still experiencing a degree of dyspnea. On arrival, you turn over care to the awaiting triage nurse without incident.

Recording Time: 15 Minutes

Respirations	26 breaths/min, clear bilaterally
Pulse	Strong and regular, 142 beats/min
Skin	Warm and dry
Blood pressure	134/82 mm Hg
Oxygen saturation (Spo₂)	95% on 100% oxygen

7. Should paramedic backup have been requested for this patient?
8. Should this patient have received an IV line?

reasonably convenient and easy to use, but they are rarely used during emergency care.

Other dry-powder devices require the patient to insert a capsule of powdered medication, which is then pierced when the patient compresses a button or lever on the device. The patient sucks the powder out using a technique similar to that previously described.

Consider Fluid Balance

Rehydration is supplemental therapy for patients with respiratory problems who are dehydrated (for example, some patients who have pneumonia or asthma). It is common practice to give a fluid bolus to younger patients with these conditions. In any older adult or other patient with cardiac dysfunction, administering too much fluid could cause pulmonary edema. Always assess breath sounds *before* and *after* giving a fluid bolus to make certain the patient does not become overhydrated. Of course, patients who have respiratory problems can quickly become extremely ill, and you will almost always want to have an IV line in place as a medication route.

Support or Assist Ventilation

If the patient becomes fatigued, breathing might need to be supported more aggressively. Therapy using continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BPAP) is becoming increasingly common and can preclude the need for intubation in many patients. Some patients may simply require bag-mask ventilation for a short period to reoxygenate, improve hemoglobin saturation, and reduce the partial pressure of arterial carbon dioxide (P_{aCO_2}).

Trying to assist breathing for patients who are *already breathing on their own* is one of the most difficult interventions. To avoid worsening a patient's condition, it is important to be confident in your bag-mask ventilation technique. Gastric distention and vomiting from overaggressive ventilation can complicate an already worsening situation. As always, *do no harm*.

Continuous Positive Airway Pressure

CPAP is used in two distinctly different ways: to treat obstructive sleep apnea and to treat respiratory failure. Many people with obstructive sleep

apnea wear a CPAP unit at night to maintain their airways during sleep. This type of CPAP may be applied via nasal pillows, a nasal mask, a face mask that resembles a typical mask used for bag-mask ventilation, or a mask that covers the entire face. This is *not* the type of CPAP used for critically ill patients. In people who are not critically ill, the positive pressure delivered maintains the stability of the posterior pharynx, thereby preventing obstruction of the upper airway when the person sleeps. This pressure limits hypoxic episodes and snoring.

The CPAP used as therapy for respiratory failure is almost always delivered through a mask that is secured to the face by some type of strap. When positive-pressure ventilation (that is, with a pocket mask or bag-mask ventilation) is given, air is forced into the upper airway and flows into the trachea and esophagus unless steps are taken to help direct it into the trachea (**FIGURE 17-19**). Indeed, positive-pressure ventilation with bag-mask ventilation or a pocket mask is physiologically the opposite of normal (negative-pressure) ventilation.

Using a bag-mask device for ventilation produces positive pressure in the chest. The more forcefully the bag is squeezed, the higher the pressure. Pressure that is too high can cause several problems. Simple pneumothorax can evolve into tension pneumothorax, air leaks can produce huge amounts of subcutaneous air, and high intrathoracic pressure can retard, or even completely

FIGURE 17-19 Positive-pressure ventilation is physiologically the opposite of normal ventilation. Air is pushed into the respiratory tract with bag-mask ventilation and can enter the esophagus and stomach unless careful technique is used.

© Jones & Bartlett Learning.

block, venous return. In recent years, prehospital providers have begun to understand the ramifications of positive-pressure ventilation during low-flow states such as shock and cardiac arrest. This understanding has resulted in CPR guidelines that stress lower ventilation rates, smaller volumes, and lower pressures. CPR is based on principles of hemodynamics, and the rate, volume, and pressure of delivered breaths can quickly do more harm than good during resuscitation.

Similarly, administering CPAP increases pressure in the chest. If the patient's blood pressure is already low, too much CPAP can stop venous return to the heart and cause a sudden decrease in blood pressure. This problem is uncommon with lower levels of CPAP, but blood pressure should be carefully monitored whenever CPAP is used (especially at levels greater than 10 cm H₂O). Keep in mind that CPAP can turn a simple pneumothorax into a tension pneumothorax in only a few breaths.

Ensure a good seal with minimal leakage (**FIGURE 17-20**). In the field, 100% supplemental oxygen is the most common driving gas for the positive pressure. Be vigilant about monitoring the gas supply—depending on the flow and the patient's respiratory rate, some CPAP units may empty a D cylinder in as little as 5 or 10 minutes. The mask is fitted with a pressure-relief valve that determines the amount of pressure delivered (such as 5 cm H₂O). The effect is similar to being in a gale-force wind (high inspiratory flow) and having to push a

pressure valve open with exhalation. This would seem to require a great deal of effort and tire out a patient in decompensating respiratory failure, but many patients in critical condition make a dramatic turnaround when CPAP is applied.

Sometimes patients find the CPAP mask claustrophobic and fight its application. Some patients can be talked through the mask application with good results, but other patients simply cannot tolerate the mask. Don't struggle with a patient who is unwilling to use the mask; doing so will increase the patient's anxiety, cardiac workload, and cardiac oxygen consumption. When CPAP works as intended, it can provide dramatic relief and avoid intubation. When it fails, it is critical to recognize a deteriorating condition and be prepared to move to the next step. Within several minutes of application, the patient's oxygen saturation should increase and the respiratory rate should decrease. The success of CPAP is inversely related to the patient's respiratory rate soon after its application. If this rate *increases*, the therapy is likely to fail; if this rate *decreases*, the therapy is likely to succeed.

Bilevel Positive Airway Pressure

In BPAP, one pressure can be delivered during inspiration (inspiratory positive airway pressure) and a different pressure can be delivered during exhalation (expiratory positive airway pressure). Instead of delivering 20 cm H₂O as in CPAP, BPAP set at 20/8 gives 20 cm H₂O pressure during inhalation and 8 cm H₂O pressure during exhalation. Because this type of positive airway pressure is more like normal breathing, it is often more comfortable for patients. It causes a pressure variation in the chest, which allows for more normal blood flow. The BPAP device is also more complex and expensive, and it is not commonly used in the field.

Assessment and Management of Specific Conditions

Upper or Lower Airway Diseases

Patients with obstructive airway disease typically present with signs of severe respiratory impairment. These may include one- to two-word dyspnea (able to say only one or two words between breaths), diminished or absent breath sounds, and altered mental status. The chief complaint is typically that

FIGURE 17-20 The continuous positive airway pressure used in the acute setting is usually administered via face mask, which must make a tight seal to function properly.

© Juanmonino/Getty Images.

Words of Wisdom

To determine the degree of nocturnal dyspnea, ask patients how many pillows they sleep on at night. If patients cannot breathe well while lying flat and need to adjust their sleep position to breathe, there is a problem. The greater the number of pillows needed, the greater the degree of respiratory difficulty.

of dyspnea, cough, or nocturnal dyspnea (awakens the person from sleep).

Obtain a thorough history, including any personal or family history of asthma and allergies. Determine whether the patient has had an acute exposure to any pulmonary irritant or any previous similar episodes. Ask the patient if they have ever been intubated.

Wheezing may be present in all types of obstructive lung disease. Look for retractions and the use of accessory muscles. Use a peak flowmeter to establish the baseline expiratory airflow and a pulse oximeter to document the degree of hypoxemia and response to therapy. Remember that the pulse oximeter is designed to detect gross abnormalities, not subtle changes.

Begin management of obstructive airway disease by placing the patient in a position of comfort. Consider calling early for paramedic backup if the patient is in severe distress. Monitor the airway, apply high-flow oxygen, and assist ventilation if needed. Use humidified oxygen if available. Establish IV access and provide circulatory support. IV therapy may be necessary to improve hydration and to thin and loosen mucus. Assist patients with their MDIs as needed. Continue monitoring and transport the patient to the closest appropriate facility. Contact medical control for further orders. Airway problems can be very frightening. Provide psychological support en route to the hospital.

Acute Pulmonary Edema

Dyspnea caused by acute pulmonary edema may be associated with cardiac disease or direct lung damage. In either case, administer 100% oxygen and, if necessary, carefully suction any secretions from the airway. Place the patient in a position of comfort. Provide assisted ventilation as needed. CPAP has proven to be immensely beneficial to patients

experiencing respiratory distress from obstructive pulmonary disease and acute pulmonary edema. Establish IV access. Monitor flow rates carefully to avoid fluid excess, which will exacerbate the patient's pulmonary edema. Consider calling for paramedic backup for intubation and provide prompt transport.

Aspiration

The inhalation of anything other than gases is called **aspiration**. Patients can aspirate fresh or salt water, blood, vomitus, or food. Patients who receive tube feedings are at particular risk for aspiration if they are placed supine immediately after receiving a large feeding. Aspiration is associated with a high mortality rate. It is a common but profoundly dangerous complication in patients who have had cardiac arrest and in patients who are unresponsive as a result of trauma or overdose. Such patients are at risk for aspirating vomitus. The aspiration of stomach contents carries the additional risk of aspiration **pneumonitis**, in which the gastric acid irritates lung tissue. This risk is in addition to the risk of pneumonia from any bacteria in the aspirated material.

Aspiration of foreign bodies, such as nuts or broken teeth, may also occur. Most adults choke only when they are intoxicated or traumatized or have a reduced gag reflex from a stroke or aging. Chronic aspiration of food is also a common cause of pneumonia in older patients.

Follow these guidelines when treating patients at risk for aspiration or who have aspirated:

1. Aggressively reduce the risk of aspiration by avoiding gastric distention when ventilating.
2. Aggressively monitor patients' ability to protect their own airway, and protect patients' airway with an advanced airway when needed.
3. Aggressively treat aspiration with suction and airway control if steps 1 and 2 fail.

Patients at risk for aspiration should not eat when they are having difficulty breathing.

Chronic Obstructive Pulmonary Disease

Patients with COPD may have an altered level of consciousness or be unresponsive from hypoxia or from carbon dioxide retention. Patients with COPD often find breathing difficult when lying down.

Assist with the patient's prescribed inhaler if there is one. Often, a patient with COPD will overuse an inhaler, so watch for side effects. Transport patients with COPD as promptly as possible to the emergency department, allowing them to sit upright if this is most comfortable.

Words of Wisdom

While one AEMT is getting oxygen ready, the second AEMT should try to coach the patient with asthma or COPD to use pursed lip breathing. This further opens the bronchioles to help air to escape.

Auto-PEEP

Not everyone should be ventilated the same way. When ventilating a patient who has severe obstructive disease, such as patients with decompensated asthma or COPD, remember the difficulty exhaling. Complete exhalation must be allowed before the next breath is delivered or pressure in the thorax will continue to rise. This phenomenon, which is called auto-PEEP (positive end-expiratory pressure), can eventually cause a pneumothorax or cardiac arrest. If the pressure in the chest exceeds the pressure of blood returning to the heart, limiting venous return, cardiac arrest may occur.

Patients in whom auto-PEEP is a concern should be ventilated at a rate of as little as 4 to 6 breaths/min. Such restraint is difficult, but it is an absolute necessity to avoid the dire consequences of raising the thoracic pressure with each breath. Remember that the standard ventilation rate for adults in cardiac arrest is only 10 breaths/min in patients without COPD.

Asthma

Many lung problems are incorrectly labeled “asthma”; therefore, your assessment of the patient is critical. Asthma is often a recurring pathologic condition. Confirm whether the patient is able to breathe normally at other times. If possible, ask family members to describe the patient's asthma. Even if they only identify wheezing as a problem, be aware that some forms of heart failure, foreign body aspiration, toxic fumes inhalation, or allergic reactions may cause wheezing.

FIGURE 17-21 The asthma triad demonstrates the three primary components of asthma and the corresponding treatments for each component. Asthma presents differently in different people, so individual treatments need to vary as well.

© Jones & Bartlett Learning; © Scott Rothstein/Shutterstock.

Bronchial asthma is characterized by an increased reactivity of the trachea and bronchi to a variety of stimuli. The hyperreactivity results in widespread, reversible narrowing of the airways, or bronchospasm. Three components of asthma are bronchospasm, airway edema, and increased mucus production (**FIGURE 17-21**). Asthma makes it difficult to exhale. Air is trapped in the distal portions of the lung and does not allow air from the next inhalation to enter the alveoli.

As you assess the patient's vital signs, note that the pulse rate will be normal or elevated, the blood pressure may be slightly elevated, and respirations will be increased. Ask questions about how and when the symptoms began.

Asthma is a common childhood illness. When you are assessing a pediatric patient, look for retraction of the skin above the sternum and between the ribs. Retractions are typically easier to see in children than in adults. Cyanosis is a late finding in children. Keep in mind that a cough may not be a symptom of a cold; it could signal pneumonia or asthma. Even if you do not hear much wheezing, the presence of a cough can indicate some degree of reactive airway disease (for example, asthma or bronchiolitis).

As you care for the patient, be prepared to suction and to administer oxygen. Allow some time for oxygenation between suction attempts. If the

patient is unresponsive, you may have to provide airway management.

If the patient has medication, such as an inhaler for an asthma attack, you may help with its administration or administer nebulized medication, as directed by local protocol. Even patients who use their inhaler may continue to get worse. Reassess breathing frequently and be prepared to assist ventilations with a bag-mask device in severe cases. If you must assist ventilations in a patient who is having an asthma attack, use slow, gentle breaths. Remember, the problem in asthma is getting the air out of the lungs, not into them. Resist the temptation to squeeze the bag hard and fast. Always assist with ventilations as a last resort, and then provide only about 10 to 12 shallow breaths/min.

The emergency care of a child with shortness of breath is the same as it is for an adult, including the use of supplemental oxygen. However, many small children will not tolerate (or may refuse to wear) a face mask. Rather than fighting with the child, hold the oxygen mask in front of the child's face or ask the parent to hold the mask (**FIGURE 17-22**). Many children with asthma have home nebulizers and are familiar with them. Administering a treatment with a bronchodilator may stabilize the event.

Status asthmaticus is a severe, prolonged asthmatic attack that cannot be stopped with conventional treatment. *It is a dire medical emergency.* Just as people with COPD ordinarily do not call for an ambulance unless their condition has markedly

FIGURE 17-22 Because children may refuse to wear an oxygen mask, you may have to hold the mask in front of the child's face. If the child still refuses, enlist the parent's help.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

changed, people with asthma do not usually dial 9-1-1 unless the attack is much worse than usual. It is reasonable to assume that *any person with asthma who feels sick enough to call an ambulance may be in status asthmaticus until proved otherwise.*

On examination, a patient in status asthmaticus will be desperately struggling to move air through obstructed airways, with prominent use of the accessory muscles of breathing. The chest will be maximally hyperinflated. Breath sounds and wheezes may be entirely inaudible because air movement is negligible, and the patient will usually be exhausted, severely acidotic, and dehydrated.

The effort to breathe during an asthma attack is very tiring, and the patient may be exhausted by the time you arrive at the hospital. An exhausted patient may have stopped feeling anxious or even struggling to breathe. This patient is not recovering; the patient is at a very critical stage and is likely to stop breathing. Aggressive airway management, oxygen administration, and prompt transport are essential in this situation. Paramedic backup should be considered. Follow local protocol.

Anaphylactic Reactions

In severe anaphylactic reactions, first remove the offending agent. Maintain the airway—the airway is always a priority regardless of the situation. If the patient is still awake, allow the patient to assume a position that does not compromise breathing. Use an appropriate oxygen device for supplemental oxygen administration, and consider early transport. Be prepared to assist breathing as needed. Epinephrine is the treatment of choice. Rapid transport and the early administration of epinephrine, if allowed by protocol, should be a priority. Because epinephrine has immediate action, it can rapidly reverse the effects of anaphylaxis. Management of anaphylaxis is covered in detail in Chapter 22, *Immunologic Emergencies*.

Spontaneous Pneumothorax

Management of a spontaneous pneumothorax begins with the ABCs. Provide airway and ventilatory support, including high-flow oxygen and assisting ventilation as needed. Be alert for the signs of the development of a tension pneumothorax.

Consider IV initiation if severe symptoms are present. Pharmacologic interventions are not

typically necessary, because the patient is generally treated symptomatically. Place the patient in a position of comfort and transport to the closest appropriate facility. The patient's condition should determine the transport mode. Provide reassurance en route. Consider calling for a paramedic unit if the patient shows signs of developing a tension pneumothorax.

Pleural Effusion

Treatment of pleural effusion consists of removal of fluid collected outside the lung, which must be performed by a physician in a hospital setting. However, you should provide oxygen and other routine support measures to these patients.

Pulmonary Embolism

Manage the airway and provide high-flow oxygen, assisting ventilation as needed. Initiate CPR if the patient is pulseless and apneic. Establish an IV line with a bolus of an isotonic crystalloid solution, and give fluid for hydration based on clinical symptoms. Other interventions are supportive, and the most severe cases will be managed as a cardiac arrest of unknown origin. Transport the patient in the appropriate mode to the most appropriate facility. Offer reassurance and psychological support en route. Call for paramedic backup if needed.

Hyperventilation

The decision whether hyperventilation is caused by a life-threatening illness or a panic attack should not be made outside the hospital. All patients who are hyperventilating should be given supplemental oxygen and transported to the hospital.

Management of hyperventilation syndrome depends on the cause of the syndrome. Oxygen should never be withheld from any patient complaining of dyspnea. The rate of oxygen administration is based on symptoms and pulse oximetry readings. Remember that factors such as carbon monoxide toxicity, which could also result in hyperventilation, may produce a falsely high oxygen saturation reading. If, through the patient's history, anxiety-related hyperventilation is confirmed, coached ventilation should be considered. When in doubt, always provide 100% oxygen.

Interventions for circulatory support and pharmacologic interventions are rarely required.

Provide psychological support for the patient with anxiety-related hyperventilation. Have the patient mimic your respiratory rate and volume. Never place a paper bag over a hyperventilating patient's mouth and nose; if the hyperventilation is the result of hypoxia or other life-threatening condition, rebreathing carbon dioxide could be lethal. Provide transport to the closest appropriate facility; the patient's condition determines the transport mode.

Obstruction of the Airway

If the patient is a small child or someone who was eating just before dyspnea developed, you may assume that the problem is an inhaled or aspirated foreign body. If the patient is old enough to talk but cannot make any noise, upper airway obstruction is the likely cause.

Upper airway obstruction may be either partial or complete. If your patient is able to talk and breathe, the wisest course may be to provide supplemental oxygen and transport carefully in a position of comfort to the hospital. As long as the patient is able to obtain sufficient oxygen, avoid doing anything that might turn a partial airway obstruction into a complete airway obstruction.

No condition is more immediately life threatening than a complete airway obstruction. The obstructing body must be removed before any other actions will be effective. Clear the patient's upper airway according to basic life support guidelines. Opening the airway with the head tilt–chin lift maneuver (or the jaw-thrust maneuver for patients with suspected spinal trauma) may solve the problem. You should perform this maneuver only after you have ruled out a head or neck injury. If simply opening the airway does not correct the breathing problem, you will have to assess the upper airway for the obstruction. Then, whether or not you are successful in clearing the airway, administer supplemental oxygen and transport the patient promptly to the emergency department.

Environmental/Industrial Exposure

In many cases, industrial sites have their own medical/fire/hazardous materials teams that are familiar with all the chemicals used at their site and know what to do in case of exposure. They will begin immediate decontamination and medical

care. In these cases, the patient needs to undergo decontamination by trained responders prior to you taking responsibility.

After the patient is decontaminated, gather information from the first responders about the substance and the cause of dyspnea. Assess the patient, paying special attention to lung sounds. Inhalation injuries can cause aspiration pneumonia that can result in eventual pulmonary edema. The inhaled substance can also cause lung damage. Blood coming from the airway is a particularly ominous sign.

Provide 100% supplemental oxygen or assisted ventilation if breathing is impaired (there is reduced tidal volume). If the upper airway is compromised, aggressive airway management (such as intubation or a cricothyrotomy by a paramedic) may be required.

Safety

The most important aspect of treatment in toxic inhalations is to remove the patient from the toxic environment, but do not enter a known toxic environment without protective breathing apparatus.

Age-Related Assessment and Management

Bronchiolitis

The treatment of infants and young children with bronchiolitis is entirely supportive. Leave the patient in a position of comfort (eg, in the caregiver's arms, if the child does not seem to be in respiratory failure) and provide supplemental oxygen. Be prepared to assist ventilation with a bag-mask device or call for paramedic backup for endotracheal intubation if needed.

Respiratory Syncytial Virus

When you are assessing a child, look for signs of dehydration. Infants with RSV often refuse liquids and become dehydrated. Treat airway and breathing problems as appropriate. Humidified oxygen is helpful, if available.

Croup

As mentioned earlier, croup often responds well to the administration of humidified oxygen. Allow

Words of Wisdom

Immunizations have substantially reduced the incidence of many infectious diseases, such as diphtheria; however, an increasing number of people in the United States do not receive immunizations (because of poverty, lack of access to health care, geographic isolation) or refuse to be immunized (because of fears that immunizations cause other diseases or beliefs that immunizations are unnecessary), causing the resurgence of some diseases. In addition, because the effects of immunizations do not last forever, conditions such as epiglottitis may be seen (albeit rarely) in adults in their 20s and 30s.

the patient to assume a position of comfort, and avoid agitating the patient. Administer nebulized epinephrine if dictated by local protocol. Transport rapidly to an appropriate facility.

Epiglottitis

Treat children with epiglottitis gently and try not to do anything that will make them cry. Keep them in a position of comfort and administer high-flow oxygen. *Do not* put anything in their mouths because this could create a complete airway obstruction. Treatment of an adult patient with potential epiglottitis should be focused on maintaining a patent airway.

Pneumonia

Management of pneumonia includes monitoring the ABCs and providing high-flow oxygen and ventilatory support as needed. Administration of IV fluids may improve hydration and thin and mobilize mucus. If a high fever is present, cool the patient. Transport to the closest appropriate facility while providing psychological support.

Pertussis

Some infants and younger children with pertussis should be treated in a hospital because they are at greater risk for complications such as pneumonia, which occurs mostly in children younger than 1 year. In infants younger than 6 months, pertussis can sometimes be life threatening.¹³

Children with pertussis may vomit or not want to eat or drink. Watch for signs of dehydration. You

may have to suction thick secretions to clear the airway. Give oxygen by the most appropriate means.

Pertussis in adults or geriatric patients does not cause the typical whooping illness that it does in infants and toddlers. However, it can cause a very severe upper respiratory infection, which in older people can result in pneumonia. The infection can cause coughing spells that last for weeks and can be so severe that patients find it hard to breathe, eat, or sleep. In the worst cases, coughing can result in cracked ribs. For patients who are already weak from other chronic conditions, pertussis can result in hospitalization. The disease has become a serious enough issue that physicians are becoming more aggressive about immunizing adults with the pertussis vaccine.

Pertussis is easily prevented with a vaccine. All AEMTs should check their immunization status and/or get a booster.

Airway Obstruction

If there is evidence of a partial or complete airway obstruction in a young child, especially a crawling baby, consider that the child may have swallowed and choked on a small object. One sign of aspiration may be an abnormality in the voice. Perform the appropriate airway clearing technique; if the patient is a child, use techniques specific to the child's age. Provide oxygen and transport any patient with a suspected aspiration. A radiograph will be needed to confirm the aspiration, its location, and the treatment.

Heart Failure

When patients with heart failure decompensate, they will often experience pulmonary edema, as fluid backs up in their circulatory system and into the lungs. High blood pressure and low cardiac output often trigger this flash (sudden) pulmonary edema. These patients are among the most sick, frightened, and worrisome patients you will encounter. They are literally drowning in their own fluid. In addition to the classic signs of respiratory distress, they may have pink, frothy sputum coming from the mouth. They will have adventitious breath sounds, most often wet (crackles, rhonchi) but sometimes dry sounding (wheezes). Their legs and feet may be swollen (pedal edema) from the backup of fluid. You might find the patient has cool,

diaphoretic, cyanotic skin. The patient's pulse will be tachycardic. The patient may have hypertension early, followed by deterioration to hypotension as a late finding.

Treatment should consist of airway, ventilatory, and circulatory support. Provide oxygen with adjuncts appropriate to the patient's condition, and prepare for the next level of deterioration. CPAP is often indicated for patients who have moderate to severe respiratory distress from an underlying disease, such as pulmonary edema from heart failure or obstructive pulmonary disease, and are alert and able to follow commands.

Tracheostomy Dysfunction

Children with chronic pulmonary medical conditions may use a home ventilator that is connected by a tracheostomy tube. This tube is placed in an opening in the neck (stoma) and can sometimes become obstructed by secretions, mucus, or foreign bodies. Other tracheostomy tube complications include bleeding, leaking, dislodgement, and infection. Your main goal is to establish a patent airway. Place the patient in a position of comfort and provide suctioning to clear the obstruction. If you are unable to clear the airway, consider paramedic intervention. After the obstruction is clear, oxygenate the patient and treat based on the patient's presentation.

Geriatric patients may have a tracheostomy tube in place because of airway obstruction, laryngeal cancer, severe infection, trauma, or the inability to manage secretions. As with children, in geriatric patients, the tube can become obstructed by secretions, foreign bodies, or airway swelling. The stoma itself can become infected. Establishing airway patency is the immediate goal.

Epidemic and Pandemic Considerations

An **epidemic** occurs when new cases of a disease occur in a human population and substantially exceed what is "expected," based on recent experience. A pandemic is an outbreak that occurs on a global scale. A pandemic occurs when a new virus emerges for which people have little or no immunity. The disease can spread easily from person to person, cause serious illness, and be found in

Words of Wisdom

The first vaccines to protect against COVID-19 infection were approved for use in the United States in December 2020. While vaccine development for a new viral strain typically takes a decade or longer, the process was expedited in response to the COVID-19 pandemic, both by allocating vast resources to the vaccines' development and by capitalizing on research already completed on similar strains of the coronavirus.

multiple countries in a short time, such as seen in 2020 with COVID-19. Obviously, there would be no specific vaccine immediately available.

Many potentially serious diseases can be passed by the respiratory route; therefore, you need to be especially compliant with wearing of PPE (gloves, eye protection, and HEPA respirator at a minimum). Viruses can live for several days on surfaces, so frequent handwashing is also important. Maintain your vaccinations and stay up to date on the latest Centers for Disease Control and Prevention recommendations. Place a surgical mask on patients with suspected or confirmed respiratory disease. Wear a HEPA respirator during any aerosol-generating procedures such as suctioning of airway secretions, CPR, and when assisting with endotracheal intubation.

COVID-19

Coronavirus disease 2019 (COVID-19) is a contagious respiratory illness that is easily transmissible from person to person. The virus that causes COVID-19 is a new form of coronavirus (SARS-CoV-2) first identified during an investigation into an outbreak in Wuhan, China. COVID-19 spreads through respiratory droplets, the same way influenza and other respiratory diseases spread.

Symptoms of COVID-19 appear 2 to 14 days after exposure and present with a wide array of potential signs and symptoms. The following list is not all inclusive. Patients may present with signs and symptoms not included here.

- Fever or chills
- Cough
- Sore throat
- Dyspnea

- Fatigue
- Congestion and/or runny nose
- Headache
- Muscle or body aches
- Loss of taste or smell
- Nausea, vomiting, diarrhea

Symptoms may range from mild to severe. Emergency warning signs requiring immediate medical attention include dyspnea, chest pain, confusion, cyanosis, and an inability to wake up or stay awake.¹⁴ Because older adults and those with serious preexisting medical conditions are at a higher risk of developing severe illness from COVID-19, treatment should be sought from the onset of symptoms.

To protect yourself from contamination with this virus, follow these suggestions:

- Avoid being exposed if possible. Wear proper PPE at all times and use additional precautions if the patient is suspected of having COVID-19.
- Wash your hands often with soap and warm water for at least 20 seconds. Use an alcohol-based hand sanitizer if soap and water are not available.
- Avoid touching your eyes, nose, and mouth with unwashed hands.
- Cover your cough or sneeze with a tissue, throw the tissue in the trash, and immediately wash your hands.
- Stay home if you are sick.
- Wear a mask that covers your mouth and nose when you are out in public.
- Avoid close contact with people who are sick and maintain a distance of 6 feet between yourself and any other person who does not live in your household.
- Get a flu shot! A flu shot will not protect against COVID-19, but if you do get the flu, your symptoms will be less severe, easing the burden on health care facilities.
- Clean and disinfect frequently touched surfaces and objects daily (eg, light switches, doorknobs, toilet handles) using household cleaning products and water.
- Clean your electronic devices (eg, phones, keyboards) with approved wipes or cleaning products.
- Always follow the manufacturer's instructions for all cleaning and disinfection products.

FIGURE 17-23 Personal protective equipment to protect against spread of COVID-19.

© Jones & Bartlett Learning.

AEMTs providing direct care for a patient with possible COVID-19 infection or who will be in the patient compartment should follow standard precautions and use the following PPE:

- **For the AEMT:**
 - Wear an N95 or higher-level respirator or, if a respirator is not available, a face mask (**FIGURE 17-23**).
 - Wear eye protection (goggles or disposable face shield that fully covers the front and sides of the face).
 - Wear a single pair of disposable patient examination gloves.
 - Wear a disposable gown for any high-contact patient-care activities, such as patient transfer onto a stretcher.
- **For the patient:**
 - Have the patient wear a face mask to help control exposure of health care personnel.

- If a nasal cannula is in place, a face mask should be worn over the nasal cannula.
- Alternatively, a nonrebreathing mask can be used if clinically indicated, but a surgical mask should be worn underneath it.
- Treatment is symptomatic. Place the patient in a position of comfort and follow local protocols.

Safety

If you suspect that a patient has an airborne disease, place a surgical mask on the patient. When you have specific reason to suspect tuberculosis, do this and also place a high-efficiency particulate air (HEPA) respirator on yourself.

YOU are the Provider SUMMARY

1. What are some potential causes of shortness of breath in older adults?

Some possible causes of shortness of breath in geriatric patients are the possibility of a foreign body airway obstruction, an acute disease process such as asthma, anaphylaxis, chronic conditions such as COPD and chronic bronchitis, and myocardial infarction. Because myocardial infarction is a possible cause, you must request paramedic intercept for the purpose of cardiac monitoring to ensure that no substantial dysrhythmias are present. Also, never rule out the possibility of a toxic exposure; however, in this case, that possibility is unlikely because no other patients are experiencing breathing difficulty.

2. What equipment would you need immediately after you arrive on scene?

Because you can never be sure of what you may encounter, you should take in all equipment you believe that you will need based on dispatch information and your company's policy. In a situation such as shortness of breath, you should take in supplemental oxygen, masks such as nasal cannulas and nonrebreathing masks, nebulized medications, and an appropriate-size bag-mask device.

3. What would your next course of action be?

The next course of action for this patient will depend on local protocols. If allowed per protocols, the administration of an inhaled beta agonist such as albuterol should be considered based on the patient's presentation and wheezing.

4. Should this patient be loaded on the stretcher and treated in the ambulance, or should you treat her at the scene?

This patient needs immediate treatment. She has an acute respiratory problem associated with cyanosis. Initiate treatment and then consider moving the patient while she is receiving the medication. Make every effort to treat an acute respiratory problem immediately and then provide transport.

5. How can you explain the patient's elevated heart rate?

This patient's elevated heart rate can be attributed to two causes. The first cause is a compensatory mechanism, which is a result of the dyspnea. To increase oxygenation, the body has increased the heart rate to circulate the available oxygen faster. The second likely cause is the administration of albuterol. Tachycardia is a common side effect of inhaled beta agonists.

6. With this patient's history of COPD, should you be concerned about the hypoxic drive?

You should never withhold oxygen from a patient who needs it for fear of depressing or stopping breathing, even in patients with COPD. Even though this patient has a history of COPD, she is experiencing a hypoxic episode and needs supplemental oxygen.

7. Should paramedic backup have been requested for this patient?

Paramedic backup should always be considered for patients reporting shortness of breath. Paramedics may be able to provide different medications for the patient's condition and provide endotracheal intubation, if needed. Also, paramedic backup should be requested to address any underlying cardiac condition that may have triggered this episode of dyspnea.

8. Should this patient have received an IV line?

Rehydration is supplemental therapy for patients with respiratory problems who are dehydrated, such as for some patients who have pneumonia or asthma. It is also useful to thin mucus secretions in those with reactive airway diseases. It is common practice to give a fluid bolus to younger patients with these conditions. However, any geriatric patient or patient who has a cardiac dysfunction could be pushed into pulmonary edema by too much fluid. Always assess breath sounds before and after giving a fluid bolus to make certain you have not overhydrated the patient. Of course, patients who have respiratory problems can quickly become ill, and you will almost always want to have an IV line in place.

Narrative

Medic One responded to an assisted living center for a patient with dyspnea. Caregiver advised EMS that the patient has been short of breath $\times$ 2 days but refused to go to the hospital. She has a prior Hx of HTN, emphysema, and asthma. EMS found pt sitting in tripod position on the edge of her bed in obvious respiratory distress. Pt AO $\times$ 3, but lethargic and slow to respond to questions. Pt presents with wheezes in upper lobes and diminished breath sounds in both lower lobes. On arrival pt on O₂ @ 4 L/min via NC with an Spo₂ of 91%. Placed pt on O₂ via NRM @ 15 L/min. Skin warm and dry with bounding radial pulses at 148 bpm. Pt has good ROM in all extremities and no peripheral edema noted. Placed pt on stretcher in position of comfort and initiated nebulized treatment of albuterol per protocol. Established 20 g IV left AC with NS TKO. Pt stated breathing was "better" after nebulized tx, but still dyspneic and wheezes still present in upper lobes. Requested orders for second nebulized albuterol treatment but denied due to pt's persistent tachycardia. Provided rapid transport to the ED for evaluation. Gave report to triage nurse and returned to service.

End of report

Prep Kit

Ready for Review

- Dyspnea is a common complaint that may be caused by numerous medical problems, including infections of the upper or lower airways, acute pulmonary edema, COPD, spontaneous pneumothorax, asthma or allergic reactions, pleural effusions, mechanical obstruction of the airway, pulmonary embolism, and hyperventilation.
- Lung disorders interfere with the exchange of oxygen and carbon dioxide that takes place during respiration through problems with ventilation, diffusion, perfusion, or a combination of these.
- Signs and symptoms of breathing difficulty include adventitious breath sounds, nasal flaring, pursed lip breathing, cyanosis, inability to talk, use of accessory muscles to breathe, and sitting in the tripod position.
- Respiratory conditions that occur more commonly in children include bronchiolitis, epiglottitis, croup, and pertussis.
- Assessment of patients in respiratory distress should be conducted as a calm, systematic process. The patients are usually quite anxious.
- Remember to use standard precautions. A patient with a respiratory emergency may have an infection that could be passed to you through sputum and/or air droplets.
- Pulmonary complaints may be associated with exposure to a wide variety of toxins. Suspect toxic inhalation if more than one patient has dyspnea, and immediately remove yourself from the scene until it is safe.
- In treating dyspnea, it is important to reassure the patient and provide supplemental oxygen. Remember to maintain the patient in a position that is comfortable for breathing, usually sitting upright.
- If the patient is not breathing or is breathing inadequately, administer 100% oxygen. You may need to provide positive-pressure ventilations with a bag-mask device. Establish IV access and administer fluids as needed.
- You will need to listen to the patient's breath sounds. Listen for a full respiratory cycle. You want to hear clear flow of air in both lungs. Not hearing the flow of air is considered an absent lung sound. The lack of air movement in the lung is an important finding.
- Crackles are the fine, crackling sounds of air trying to pass through fluid in the alveoli, typically heard on inspiration. These are often a result of pulmonary edema, or fluid in the lungs caused by heart failure.
- Rhonchi are lower-pitched sounds caused by secretions or mucus in the larger airway. These can be heard with infections such as pneumonia and bronchitis, or in cases of aspiration.
- Stridor is a high-pitched sound heard on inspiration as air tries to pass through an obstruction in the upper airway. This sound indicates a partial obstruction of the trachea and is seen in patients with anatomic or foreign body airway obstruction.
- Wheezing is a high-pitched whistling sound typically heard on expiration. It indicates constriction and/or inflammation in the bronchus and may be heard in patients with asthma or COPD.
- If there are life-threatening conditions, there may not be time to take a history or perform a secondary assessment. If you can, obtain a thorough history, asking the patient to describe the problem to determine the chief complaint.
- If the patient has a prescribed inhaler or other respiratory medication, consult medical control to assist with appropriate use.
- Transport the patient to the hospital, monitoring the patient's condition en route.
- Reassess and record vital signs at least every 5 minutes for a patient in unstable condition and/or after the patient uses an inhaler.
- Consider rehydration; it is supplemental therapy for patients with respiratory problems who are dehydrated. It is common practice to give a fluid bolus to younger patients with respiratory problems, but a patient with cardiac

dysfunction could experience pulmonary edema by having too much fluid.

- Breathing may need to be supported more aggressively with continuous positive airway pressure or bilevel positive airway pressure.
- Remember that pulse oximetry readings may be inaccurate in the presence of conditions that abnormally bind hemoglobin, including carbon monoxide poisoning.

- Remember, a patient who is breathing rapidly may not be getting a sufficient amount of oxygen as a result of respiratory distress from a variety of problems. In every case, prompt recognition of the problem, giving oxygen or providing ventilatory support, and prompt transport are essential.

Vital Vocabulary

adventitious breath sounds Abnormal breath sounds such as wheezes, rhonchi, and crackles.

allergen A substance that causes an allergic reaction.

aspiration The inhalation of liquid or solid matter into the lungs through the trachea, typically as a result of an incompetent gag reflex or over-aggressive resuscitation technique; may occur when patients are unable to maintain their own airway and blood or fluid is present in the mouth.

asthma A chronic inflammatory lower airway condition resulting in intermittent wheezing and excess mucus production; muscle spasm in the small air passageways and excess mucus result in airway obstruction.

atelectasis A condition of airless or collapsed alveoli that causes pulmonary shunting, ventilation-perfusion mismatching, and possibly hypoxemia.

botulism Poisoning characterized by severe muscle paralysis and usually caused by eating food containing botulinum toxin.

bronchial breath sounds Normal breath sounds made by air moving through the bronchi.

bronchiolitis Inflammation of the bronchioles that usually occurs in children younger than 2 years and is often caused by the respiratory syncytial virus.

carbon dioxide retention A condition characterized by a chronically high level of carbon dioxide in blood as the result of a respiratory disease.

carpopedal spasm A contorted position of the hand or foot in which the fingers or toes flex in a

clawlike manner; may result from hyperventilation or hypocalcemia.

chronic bronchitis Irritation and inflammation of the major lung passageways, from either infectious disease or irritants such as smoke.

chronic obstructive pulmonary disease (COPD) A slow, degenerative process that causes destructive changes in the alveoli and bronchioles in the lungs.

common cold A viral infection usually associated with swollen nasal mucous membranes and the production of fluid from the sinuses.

crackles Crackling, moist breath sounds signaling fluid in the smaller air passages of the lungs; formerly called rales.

croup An infectious disease of the upper respiratory system, usually caused by a virus, that may cause partial airway obstruction and is characterized by a barking cough; usually seen in children; also referred to as laryngotracheobronchitis.

cystic fibrosis A genetic disorder of the endocrine system that makes it difficult for chloride to move through the cells; characterized by increased production of mucus in the lungs and digestive system; also called mucoviscidosis.

diffusion The movement of solutes (molecules) from an area of higher concentration to an area of lower concentration.

diphtheria An infectious disease in which a membrane lining the pharynx is formed that can severely obstruct passage of air into the larynx.

dyspnea Shortness of breath or difficulty breathing.

embolus A blood clot or other substance in the circulatory system that breaks free from its site of origin and obstructs blood flow in a distant blood vessel.

emphysema A disease of the lungs in which there is extreme dilation and eventual destruction of pulmonary alveoli with poor exchange of oxygen and carbon dioxide; it is one form of chronic obstructive pulmonary disease.

epidemic An outbreak of a disease in which new cases in a human population substantially exceed the number expected based on recent experience.

epiglottitis An acute bacterial infection that results in rapid swelling of the epiglottis and surrounding tissues; may cause upper airway obstruction; also referred to as acute supraglottic laryngitis.

Guillain-Barré syndrome A disease of unknown cause characterized by progressive paralysis moving from the feet to the head (ascending paralysis); if paralysis reaches the diaphragm, the patient may require respiratory support.

Hering-Breuer reflex The nervous system mechanism that terminates inhalation and prevents lung overexpansion.

hyperoxia An excess of oxygen.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal; may lead to increased intrathoracic pressure, decreased venous return, and hypotension when associated with bag-mask device use.

hyperventilation syndrome (panic attack) A syndrome that occurs in the absence of other physical problems and whose symptoms include anxiety, dizziness, numbness, tingling of the hands and feet, and dyspnea despite rapid breathing.

hypoventilation The movement of inadequate volumes of air into the lungs.

hypoxia A dangerous condition in which the body's tissues and cells do not have enough oxygen.

hypoxic drive A backup system that controls respirations by sensing when the oxygen level in the blood falls.

influenza type A (flu) A virus that has crossed the animal/human barrier and has infected humans, recently reaching a pandemic level with the H1N1 strain.

inspiratory/expiratory (I/E) ratio An expression for comparing the length of inspiration with that of expiration, normally 1:2, meaning that expiration is twice as long as inspiration (not measured in seconds).

meningococcal meningitis An inflammation of the meningeal coverings of the brain and spinal cord; can be highly contagious.

metered-dose inhaler (MDI) A miniature spray canister used to direct medications through the mouth to be inhaled into the lungs.

methicillin-resistant *Staphylococcus aureus* (MRSA) A bacterium that can cause infections in different parts of the body and is often resistant to commonly used antibiotics; it is transmitted by different routes, including the respiratory route, and can be found on the skin, in surgical wounds, and in the bloodstream, lungs, and urinary tract.

orthopnea Severe dyspnea experienced when lying down that is relieved by a change in position, such as sitting up or standing.

pandemic An outbreak of a disease that occurs on a global scale.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

pertussis (whooping cough) An airborne bacterial infection that affects primarily children younger than 6 years; patients will be feverish and exhibit a "whoop" sound on inspiration after a coughing attack; highly contagious through droplet infection.

pleural effusion A collection of fluid between the lung and chest wall that may compress the lung.

pleural friction rub A squeaking or grating sound that occurs when the pleural linings rub together, which may be heard on inspiration, expiration, or both; commonly caused by inflammation of the pleura.

pleuritic chest pain Sharp, stabbing pain in the chest that is worsened by a deep breath or other chest wall movement; often caused by inflammation or irritation of the pleura.

pneumonia An infectious disease of the lung that damages lung tissue.

pneumonitis Lung inflammation from an irritant, such as a chemical, dust, or radiation, or from aspiration, such as aspiration of gastric contents.

pneumothorax A partial or complete accumulation of air in the pleural space.

pulmonary edema A buildup of fluid in the lungs, usually as a result of left-side heart failure.

pulmonary embolism A blood clot that breaks off from a large vein and travels to the blood vessels of the lung, causing obstruction of blood flow.

purulent Full of pus; having the character of pus.

respiration The inhaling and exhaling of air; the physiologic process that exchanges carbon dioxide from fresh air; also, the exchange of gases that occurs at the pulmonary and cellular levels.

respiratory acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by accumulation of acids in the body from a respiratory cause such as inadequate ventilation.

respiratory alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a respiratory cause such as overaggressive ventilation.

respiratory syncytial virus (RSV) A virus that causes an infection of the lungs and breathing passages; can result in other serious illnesses that affect the lungs or heart, such as bronchiolitis and pneumonia; highly contagious and spread through droplets.

retractions Movements in which the skin pulls in around the ribs during inspiration; the drawing in of the intercostal muscles and the muscles above the clavicles that can occur in respiratory distress.

rhonchi Coarse, low-pitched, rattling breath sounds heard in patients with chronic mucus in the upper airways.

severe acute respiratory syndrome (SARS I) A potentially life-threatening viral infection that usually starts with flulike symptoms.

small-volume nebulizer A respiratory device that holds liquid medicine that is turned into a fine mist. The patient inhales the medication into the airways and lungs as a treatment for conditions like asthma.

spacer A device that collects medication as it is released from the canister of a metered-dose inhaler, allowing more medication to be delivered to the lungs and less to be lost to the environment.

status asthmaticus A prolonged exacerbation of asthma that does not respond to conventional therapy.

stridor A harsh, high-pitched respiratory sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

tachypnea Rapid respiratory rate.

tuberculosis A chronic bacterial disease, caused by *Mycobacterium tuberculosis*, that usually affects the lungs but also can affect other organs such as the brain and kidneys; it is spread by cough and can lie dormant in a person's lungs for decades and then reactivate.

ventilation The exchange of air between the lungs and the air of the environment, spontaneously by the patient or with assistance.

vesicular breath sounds Normal breath sounds made by air moving in and out of the alveoli.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Chapter 18

Cardiovascular Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Pathophysiology

Applies comprehensive knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Cardiovascular

Anatomy, signs, symptoms, and management of

- Chest pain (pp 963–968)
- Cardiac arrest (pp 951, 952, 969–972)

Anatomy, physiology, pathophysiology, assessment, and management of

- Acute coronary syndrome (pp 948–956)
 - Angina pectoris (pp 948–950)
 - Myocardial infarction (pp 950–956)
- Aortic aneurysm/dissection (pp 956–963)
- Thromboembolism (p 948)
- Heart failure (pp 954–956)
- Hypertensive emergencies (p 956)

KNOWLEDGE OBJECTIVES

1. Review the basic anatomy and physiology of the cardiovascular system. (pp 941–946)
2. Discuss the regulation of heart function. (p 945)
3. Describe the cardiac cycle, including the concepts of afterload, stroke volume, and cardiac output. (pp 945–946)
4. Describe the pathophysiology of angina pectoris, thromboembolism, and myocardial infarction. (pp 948–950)
5. List the dangerous dysrhythmias that may follow a myocardial infarction. (p 952)
6. Discuss the pathophysiology of cardiogenic shock and its signs, symptoms, and treatment. (pp 952–954)
7. Discuss the pathophysiology of heart failure and its signs, symptoms, and treatment. (pp 954–956)
8. Discuss the pathophysiology of pulmonary edema. (p 956)
9. Describe the pathophysiology, signs and symptoms, and management of hypertensive emergencies. (p 956)
10. Describe the pathophysiology, assessment, and management of aortic aneurysm/dissection. (pp 956–963)

11. Explain patient assessment procedures for cardiovascular problems. (pp 957–963)
12. Explain the relationship between airway management and the patient with cardiac compromise. (pp 961–963)
13. Discuss emergency medical care for cardiovascular emergencies, including angina pectoris, thromboembolism, and myocardial infarction. (pp 948–951)
14. List the indications and contraindications for the use of nitroglycerin. (p 983)
15. Explain that many patients will have had cardiac surgery and may have implanted pacemakers. (pp 965–967)
16. Define cardiac arrest. (p 952)
17. Discuss the different types of automated external defibrillators (AEDs). (pp 969–970)
18. Describe the difference between the fully automated and the semiautomated defibrillator. (p 969)
19. List the advantages of using AEDs. (pp 969–970)
20. List the indications and contraindications for use of an AED. (pp 969–970)
21. Explain the use of remote, adhesive defibrillator pads. (pp 970, 974)
22. Explain why not all patients in cardiac arrest need to be attached to an AED. (p 970)
23. List the reasons for early defibrillation. (pp 970–971)
24. Describe AED maintenance procedures. (pp 971–972)
25. Explain the circumstances that may result in inappropriate shocks from an AED. (p 972)
26. Explain the role played by medical direction in the use of AEDs. (p 972)
27. Explain the need for a case review of each incident in which an AED is used. (p 972)
28. Discuss the importance of practice and continuing education with the AED. (p 972)
29. Explain the reason not to touch the patient, such as by delivering cardiopulmonary resuscitation, while the AED is analyzing the heart rhythm and delivering shocks. (p 971)
30. Describe the emergency medical care for the patient with cardiac arrest. (pp 972–974)
31. Explain the relationship of age to defibrillation. (p 974)
32. Discuss the procedures to follow for standard operation of the various types of AEDs. (pp 969–970)
33. Describe the components of care following AED shocks. (p 977)
34. Explain criteria for transport of the patient following CPR and defibrillation. (p 978)
35. Discuss the role of cardiac monitoring. (pp 979–980)

SKILLS OBJECTIVES

1. Demonstrate how to assess and provide emergency medical care for a patient with chest pain or discomfort. (pp 963–964)
2. Demonstrate the administration of aspirin to a patient with chest pain. (p 964)
3. Demonstrate the administration of nitroglycerin. (pp 965–966, Skill Drill 18-1)
4. Demonstrate how to perform maintenance of an AED. (pp 971–972)
5. Demonstrate how to use an AED and perform CPR. (pp 975–976, Skill Drill 18-2)
6. Demonstrate how to place electrodes for cardiac monitoring. (pp 980–982, Skill Drill 18-3)

Introduction

The American Heart Association estimates that one person has an acute myocardial infarction (AMI) in the United States approximately every 40 seconds.¹ In the United States, emergency medical services (EMS) personnel treat approximately 60% of out-of-hospital cardiac arrests each year.¹ Heart disease has been the leading cause of death of Americans since the early 1900s.^{2,3}

It is important for EMS providers to understand that many deaths caused by cardiovascular disease occur from problems that may have been avoided by people living healthier lifestyles and by access to improved medical technology. We can help to reduce these numbers of deaths with better public awareness, early access to EMS, increased numbers of laypeople trained in and willing to perform cardiopulmonary resuscitation (CPR), increased use of evolving technology in dispatch and cardiac arrest

response, public access to defibrillation devices, the recognition of the need for advanced life support (ALS) services, and transportation to hospitals that can provide coronary catheterization and post-arrest care.

This chapter begins with a brief description of the heart and how it works. It then discusses the relationship between chest pain and ischemic heart disease. It explains how to recognize and treat AMI (classic heart attack) and its complications—sudden death, cardiogenic shock, and heart failure. The use of nitroglycerin (NTG) and aspirin are described. The last part of the chapter is devoted to the use and maintenance of the automated external defibrillator (AED) and placement of electrodes for cardiac monitoring.

Anatomy and Physiology Review

Anatomy Review

The cardiovascular system consists of the heart (the pump), the blood vessels (the container), and the blood (the fluid). All components must interact effectively to maintain life.

Structures of the Heart

The **heart** is a muscular, cone-shaped organ whose function is to pump blood throughout the body (**FIGURE 18-1**). The heart muscle is referred to as the **myocardium**. The **pericardium**, or **pericardial sac**, is a thick, fibrous membrane that surrounds the heart. The pericardium is composed of the visceral layer and the parietal layer. The visceral layer of the pericardium lies against the heart and is also called the **epicardium**. The outer layer of the pericardium, the

parietal layer, is separated from the visceral layer by a small amount of **pericardial fluid** that reduces friction within the pericardial sac. The **endocardium** is the smooth inner lining of the chambers of the heart and the surface of the valves.

Two atria and two ventricles make up the upper and lower chambers of the heart, respectively. Each **atrium** receives blood that is returned to the heart from other parts of the body; each **ventricle** pumps blood out of the heart. The left ventricle is the strongest and largest of the four cardiac

FIGURE 18-1 The anterior aspect of the thorax shows the relative position of the heart beneath the surface.

YOU are the Provider

Part 1

Your ambulance is dispatched to a local residence for a woman who reports chest pain. As you arrive on scene, the patient's husband greets you at the front door and states that his wife is on the sofa, complaining of "really bad" chest pain. On walking into the residence, you find the wife in the fetal position on the sofa, rocking back and forth, moaning in pain. She states that she is 56 years old and has had multiple heart attacks in the past.

1. How does the heart become oxygenated?
2. What is the most common cause of chest pain?

Words of Wisdom

Three components are required to have adequate tissue perfusion: pump (heart), container (vessels), and fluid (blood).

chambers because it is responsible for pumping blood through blood vessels throughout the body.

Valves of the Heart

The valves of the heart include the **atrioventricular valves** (these are the **tricuspid valve** and the **mitral valve** [also known as the bicuspid valve]) and the **semilunar valves** (these are the **aortic valve** and the **pulmonic valve**) (**FIGURE 18-2**). **Papillary muscles** in the ventricles contract to tighten the **chordae tendineae**, preventing the tricuspid and mitral valve from inverting and allowing blood to flow backward into the atria during contraction of the heart.

Coronary Circulation

The heart, like any other muscle, requires oxygen and nutrients. These are supplied via the **coronary arteries**, which arise from the **aorta** shortly after it leaves the left ventricle. The coronary circulation emanates from the left and right coronary arteries (**FIGURE 18-3**).

The left main coronary artery is the largest and shortest of the myocardial blood vessels. It rapidly divides into two branches, the **left anterior descending (LAD) artery** and the **circumflex coronary artery**. These arteries subdivide further, supplying blood to most of the left ventricle, the interventricular septum (the thick walls between the ventricles), and, at times, the **atrioventricular (AV) node**.

Blood Vessels

Blood is transported through the body via the **arteries**, which carry blood away from the heart, and **veins**, which carry blood back to the heart. The aorta is the body's largest artery. Arteries become smaller as they get farther from the heart. Eventually, they branch into many small **arterioles** that divide even further into **capillaries**, which are microscopic, thin-walled blood vessels. The capillaries eventually enlarge to form **venules**, which merge and form veins.

Two large veins, the **superior vena cava** and the **inferior vena cava**, return deoxygenated blood from the body to the right atrium. The inferior vena cava is the larger of the two veins.

In the heart, blood enters the right atrium via the superior and inferior venae cavae and the **coronary sinus** (the end of the great cardiac vein), which collects blood returning from the walls of the heart. Blood from four pulmonary veins enters the left atrium (**FIGURE 18-4**).

FIGURE 18-2 Anatomy of the heart, including its valves.

FIGURE 18-3 The coronary arteries supply oxygen and nutrients to the heart. **A.** Anterior view. **B.** Posterior view.

© Jones & Bartlett Learning.

Blood and Its Components

Blood consists of **plasma** and formed elements or cells: **red blood cells (RBCs)**, **white blood cells (WBCs)**, and platelets. Plasma accounts for more

than one-half of total blood volume. RBCs (erythrocytes) carry oxygen to the tissues. These disk-shaped cells flow in the plasma, which moves them along through the circulatory system. RBCs contain the protein **hemoglobin**, which binds to oxygen and

FIGURE 18-4 Blood flow through the heart. **A.** Flow of oxygen-poor blood from the venous circulation. **B.** Flow of oxygen-rich blood from the pulmonary veins, through the left side of the heart and into the aorta.

© Jones & Bartlett Learning.

carries it to the tissues. WBCs (leukocytes) fight infection either via antibodies or direct attack on bacteria. Finally, **platelets** play an important role in the blood-clotting process (coagulation); they begin the process by clumping together, after which clotting proteins solidify the remainder of the clot.

The Electrical Conduction System

The brain partially controls the heart's rate and strength of contraction via the autonomic nervous system. However, pumping of the heart occurs in response to an electrical stimulus initiated by a group of complex electrical tissues that are part of a **conduction system**. The cardiac conduction system consists of six parts, as shown in **FIGURE 18-5**.

The **sinoatrial (SA) node**, located high in the right atrium, is the normal site of origin of the electrical impulse. It is the heart's natural pacemaker and has an intrinsic rate of 60 to 100 beats/min. If the SA node is not functioning properly, the AV node may take over as the heart's pacemaker. The intrinsic rate of the AV node is 40 to 60 beats/min. Rhythms originating below the AV node have an intrinsic rate of 20 to 40 beats/min. Impulses originating in the SA node travel through the right

and left atria, resulting in atrial contraction. The impulse then travels to the AV node, located in the right atrium adjacent to the septum, where it transiently slows. Electrical stimulation of the heart muscle then continues toward the bundle of His, which is a continuation of the AV node. From here, it proceeds rapidly to the right and left bundle branches, stimulating the interventricular septum. The impulse then spreads out through the rest of the conduction system, resulting in ventricular contraction, or systole.

Electrical Properties of Cardiac Cells

The ability of cells to respond to electrical impulses is referred to as the property of **excitability**. The ability of the cells to conduct electrical impulses is referred to as the property of **conductivity**.

Cardiac muscle cells have a special characteristic called **automaticity** that is not found in any other type of muscle cells. Automaticity allows a cardiac muscle cell to contract spontaneously without a stimulus from a nerve source. Normal impulses in the heart start at the SA node. As long as impulses come from the SA node, the other myocardial cells will contract when the impulse reaches them. If no

FIGURE 18-5 The electrical conduction system of the heart initiates an electrical impulse throughout the heart. The impulse travels through the six parts of the cardiac conduction system.

© Jones & Bartlett Learning.

impulse arrives, however, the other myocardial cells are capable of creating their own impulses and stimulating a contraction of the heart, although at a generally slower rate.

Physiology Review

Regulation of Heart Function

The electrical stimulus that causes the heart to contract originates from impulses from the brain via the **autonomic nervous system**. The heart's **chronotropic state** (control of the *rate* of contraction), **dromotropic state** (control of the *speed* of electrical conduction), and **inotropic state** (control of the *strength* of contraction) are controlled by the autonomic nervous system, the hormones of the endocrine system, and the heart tissue. See Chapter 7, *The Human Body*, for more information.

Receptors in the blood vessels, kidneys, brain, and heart constantly monitor body functions to help maintain homeostasis. **Baroreceptors** respond to changes in pressure, usually within the heart or the main arteries. **Chemoreceptors** sense changes in the chemical composition of the blood. If abnormalities are sensed, nerve signals are transmitted to the appropriate target organs, and hormones or neurotransmitters are released to correct the

situation. After conditions normalize, the receptors stop firing and the signals cease.

The Cardiac Cycle

The process that creates the pumping of the heart is known as the **cardiac cycle**. This cycle begins with myocardial contraction and concludes at the beginning of the next contraction. The heart's contraction results in pressure changes within the cardiac chambers, causing blood to move from areas of high pressure to areas of low pressure.

Systole refers to the contraction of the ventricles and the pumping of blood into the systemic circulation; during this phase, systolic blood pressure is measured. **Diastole** refers to relaxation of the heart; during this phase, diastolic blood pressure is measured.

Preload is the amount of blood returned to the heart to be pumped out and directly affects afterload. **Afterload** is the pressure in the aorta or the peripheral vascular resistance, against which the left ventricle must pump blood. The greater the afterload, the harder it is for the ventricle to eject blood into the aorta. Increased afterload can cause a reduction in **stroke volume**, or the amount of blood ejected per contraction. To a large degree, afterload is governed by arterial blood pressure.

Afterload is greater with vasoconstriction and less with vasodilation.

Cardiac output (the amount of blood pumped through the circulatory system in 1 minute) is expressed in liters per minute (L/min) and is expressed with this equation:

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

Factors that influence the heart rate, the stroke volume, or both will affect cardiac output and, thus, **perfusion** (flow of blood) to the body's tissues. The presence of pulses is a good indicator of blood pressure. Weak or absent peripheral pulses indicate decreased perfusion. Weak central pulses indicate substantial hypotension and decompensated shock.

Increased venous return to the heart stretches the ventricles to some extent, resulting in increased cardiac **contractility**. This relationship is called the **Starling law** of the heart.

The heart has several ways of increasing stroke volume. According to the Starling law, the more cardiac muscle is stretched, the greater the force with which it contracts. If an increased volume of blood is returned to the right or left side of the heart, the muscle surrounding the cardiac chambers will have to stretch to accommodate the larger volume. The more the cardiac muscle stretches, the greater will be the force of its contraction, the more completely it will empty, and, therefore, the greater the stroke volume will be. The amount of blood returning to the right atrium may vary somewhat from minute to minute, but the normal heart continues to pump out the same percentage of blood returned. This is called the **ejection fraction**. This system allows the heart to function at the same capacity regardless of changes in the body's position or what the person is doing, whether sitting, moving, sneezing, or other activity.

Blood Flow Within the Heart

Blood from the upper part of the body returns to the heart through the superior vena cava, and blood from the lower part of the body returns through the inferior vena cava. From the right atrium, blood passes through the tricuspid valve into the right ventricle. Blood is then pumped by the right ventricle through the pulmonic valve into the pulmonary artery and to the lungs. In the lungs, blood is

oxygenated and, at the same time, carbon dioxide and other waste products are removed.

Freshly oxygenated blood is returned to the left atrium through the pulmonary veins. Blood then flows through the mitral valve into the left ventricle, which pumps the oxygenated blood through the aortic valve, into the aorta, and then to the entire body. In the body, oxygen and nutrients pass out of the capillaries into the cells, and carbon dioxide and waste products pass from the cells into the capillaries in a process called diffusion.

After oxygenated blood has been delivered by the capillaries, deoxygenated blood is returned to the heart, starting from the capillaries, to the venules, and to the veins. Eventually the veins empty into the heart, then the blood is sent to the lungs to be reoxygenated and returned to the heart where the process begins again.

Pulmonary Circulation

Within the body, the **pulmonary circulation** carries blood from the right side of the heart to the lungs and back to the left side of the heart, and the **systemic circulation** from the left side of the heart is responsible for blood flow to the rest of the body. Deoxygenated blood from the right ventricle is pumped through the pulmonic valve into the pulmonary artery. This artery rapidly divides into the right and left pulmonary arteries. These arteries transport the blood to the lungs. Inside the lungs, the arteries branch out, becoming smaller and smaller. At the level of the capillary, waste products are eliminated and the blood is reoxygenated. The reoxygenated blood travels through venules into the pulmonary veins. The four pulmonary veins (two from each lung) empty into the left atrium.

Systemic Arterial Circulation

Oxygenated blood leaves the heart through the aortic valve and passes into the aorta. From the aorta, blood is distributed to all parts of the body. All arteries of the body, except the pulmonary arteries, are derived from the aorta.

Pathophysiology

Chest pain or discomfort that is related to the heart usually stems from cardiac cell **ischemia**, which is decreased blood flow to the heart muscle. Because of a partial or complete blockage of blood flow

Special Populations

The cardiovascular system is affected by aging. You should be aware of the changes, seeking to distinguish what is normal, what is chronic, and what is an acute condition for the patient. Sometimes the weakening of the heart muscle, the deterioration of its electrical conduction system, and the hardening of the arteries make the task of assessing and caring for geriatric patients more difficult.

As the heart's muscle mass and tone decrease, the amount of blood pumped out of the heart per beat is decreased. The residual (reserve) capacity of the heart is also reduced; therefore, when the vital organs of the body need additional blood flow, the heart cannot meet the increased need. If blood flow to the brain is inadequate, the patient may report weakness, fatigue, or dizziness and syncope may develop.

Under normal conditions, electrical impulses travel throughout the heart, resulting in the contraction of the heart muscle and the pumping of blood from the heart's chambers. With aging, the electrical conduction system can deteriorate, causing the heart's contraction to weaken or, if blood flow to the heart muscle is affected, extra beats to form. With decreased strength of contraction, the heartbeat is weaker and blood flow to the tissues is reduced. If extra beats are produced, the patient's heart rhythm will be irregular. Although some irregular heart rhythms are benign, others can be potentially lethal.

The arteries are also affected by aging. Arteriosclerosis (hardening of the arteries) can develop, affecting perfusion of the tissues. There is an increased chance of heart attack or stroke from decreased blood flow or plaque formation (atherosclerosis) in the narrowed arteries.

In some patients, particularly older patients with diabetes, chest pain is absent, and the clinical picture can be confused with other, noncardiac conditions.

through the coronary arteries, heart tissue fails to get enough oxygen and nutrients. The tissue soon begins to starve and eventually dies if blood flow is not restored. Therefore, ischemic heart disease is disease involving a decrease in blood flow to one or more portions of the heart muscle.

Atherosclerosis

Most often, diminished blood flow to the myocardium is caused by coronary artery **atherosclerosis**. Atherosclerosis is a disorder in which a fatty material called cholesterol and other fatty substances build up and form plaque inside the walls of blood

FIGURE 18-6 In atherosclerosis, cholesterol and other fatty substances build up inside the walls of the blood vessels, causing an obstruction in blood flow to the heart.

© Jones & Bartlett Learning.

vessels, obstructing flow and interfering with their ability to dilate or contract (**FIGURE 18-6**). Eventually, atherosclerosis can cause complete **occlusion**, or blockage, of a coronary artery. Atherosclerosis usually involves other arteries of the body, as well.

The problem begins when the first deposit of cholesterol is laid down on the inside of an artery. This may happen during the teenage years. As a person ages, more of this fatty material is deposited; the **lumen**, or the inside diameter of the artery, narrows. As the cholesterol deposits grow, calcium deposits can form as well. The inner wall of the artery, which is normally smooth and elastic, becomes rough and brittle with these atherosclerotic plaques. Damage to the coronary arteries may become so extensive that they cannot accommodate increased blood flow at times of increased need, resulting in an inappropriate circulating volume.

Arteriosclerosis can also cause a reduction in blood flow. Arteriosclerosis is a thickening of the arterial walls, which causes a loss of elasticity (hardening of the arteries).

For reasons that are still not completely understood, brittle plaque will sometimes develop a crack, exposing the inside of the atherosclerotic wall. Acting like a torn blood vessel, the jagged edge of the crack activates the blood-clotting system, just as it does when an injury has caused bleeding. In this situation, however, the resulting blood clot

Words of Wisdom

Various changes in the walls of coronary arteries can result in certain disease states. Atherosclerosis is a disorder characterized by the formation of plaques of material, mostly lipids and cholesterol, on the intima of the artery. This process gradually narrows the lumen (opening or hollow part of the artery), resulting in a reduction in arterial blood flow. Arteriosclerosis is hardening of the arteries so they cannot compensate for atherosclerosis by dilating.

will partially or completely block the lumen of the artery. If it does not occlude the artery at that location, the blood clot may break loose and begin floating in the blood, becoming a thromboembolism. A **thromboembolism** is a blood clot that is floating through blood vessels until it reaches an area too narrow for it to pass, causing it to stop and block the blood flow at that point. Tissues downstream from the blood clot will experience a lack of oxygen (hypoxia). If blood flow is resumed in a short time, the hypoxic tissues will recover. However, if too much time goes by before blood flow is resumed, the tissues become necrotic (die). If a blockage occurs in a coronary artery, the condition is known as an **acute myocardial infarction (AMI)**, a classic heart attack (**FIGURE 18-7**). Infarction means the death of tissue. The same sequence may also cause the death of cells in other organs, such as the brain. The death of

FIGURE 18-7 An acute myocardial infarction occurs when a blood clot prevents blood flow to an area of the heart muscle. If left untreated, this results in death of heart tissue.

© Jones & Bartlett Learning.

heart muscle can result in severe diminishment of the heart's ability to pump or cause it to stop completely (cardiac arrest).

In the United States, coronary artery disease is the number one cause of death for men and women³ in a typical year (although the COVID-19 pandemic skewed these numbers in 2020). Coronary artery disease can strike at any age. You must be alert to the possibility that, although less likely than in an older person, a 26-year-old person with chest pain could actually be having a heart attack, especially if they have a higher-than-usual risk.

Factors that place a person at higher risk for a myocardial infarction are called risk factors. The major controllable factors are cigarette smoking, high blood pressure, elevated cholesterol levels, an elevated blood glucose level (diabetes), lack of exercise, and stress. The major risk factors that cannot be controlled are older age, family history of atherosclerotic **coronary artery disease**, race, ethnicity, and male sex.

Acute Coronary Syndrome

Many patients who call for EMS assistance because of chest pain have acute coronary syndrome. **Acute coronary syndrome (ACS)** is the term used to describe any group of symptoms consistent with acute myocardial ischemia. Myocardial ischemia is a decrease in blood flow to the heart, which results in chest pain through reduction of oxygen and nutrients to the tissues of the heart. This can be a temporary situation known as angina pectoris, or a more serious condition, an AMI. Because the signs and symptoms of these two conditions are very similar, they are treated basically the same under the designation of ACS. To understand them better, we will discuss each one separately.

Angina Pectoris

Chest pain does not always mean that a person is having an AMI. When, for a brief period, heart tissues are not getting enough oxygen (ischemia), the pain is called **angina pectoris**, or angina. It is defined as a brief discomfort that has predictable characteristics and is relieved promptly. There is no change in the heart rhythm pattern with angina. Although it can result from a spasm of the artery (also known as vasospastic angina or Prinzmetal angina), angina is most often a symptom of atherosclerotic coronary artery disease. Angina occurs when the heart's need

for oxygen exceeds its supply, usually during periods of physical or emotional stress when the heart is working hard. A large meal or sudden fear may also trigger an attack. When the increased oxygen demand goes away (for example, the person stops exercising), the pain typically goes away.

Angina pain is typically described as crushing, squeezing, or “like somebody is standing on my chest.” It is usually felt in the midchest, under the sternum (substernal). However, it can radiate to the jaw, the arms (frequently the left arm), the mid-back, or the epigastrium (the upper-middle region of the abdomen). The pain usually lasts from 3 to 8 minutes, rarely longer than 15 minutes. It may be associated with shortness of breath, nausea, or sweating. It disappears promptly with rest, supplemental oxygen, or NTG, all of which increase the supply of oxygen to the heart. Although angina pectoris is frightening, it does not mean that heart cells are dying, nor does it usually result in death or permanent heart damage. It is, however, a warning that you and the patient should both take seriously. A single episode may be a precursor to a myocardial infarction. Even with angina, because oxygen

supply to the heart is diminished, the electrical system can be compromised and the person is at risk for substantial cardiac rhythm problems. Although chest pain may dissipate, myocardial ischemia and injury can continue.

Words of Wisdom

Prinzmetal angina is a rare chronic condition that almost always occurs when a person is at rest and usually in younger patients rather than those who have other types of angina. Attacks can be extremely painful and typically occur between midnight and early morning.

The pain from Prinzmetal angina is caused by a spasm in the coronary arteries (which supply blood to the heart muscle). The spasm may be the result of stress, smoking, cocaine use, exposure to cold weather, or medications that cause vasoconstriction. Symptoms can generally be relieved by taking medications that include calcium antagonists and nitrates. Other names for Prinzmetal angina include *variant angina*, *Prinzmetal variant angina*, and *angina inversa*.⁴

YOU are the Provider

Part 2

You perform a primary survey of the patient while your partner obtains a set of baseline vital signs; findings show a pulse rate of 74 beats/min, respirations of 24 breaths/min, a blood pressure of 146/88 mm Hg, and SpO₂ of 92% on room air. Your partner places the patient on a nonrebreathing mask at 15 L/min. On completion of your assessment you find no signs of trauma. The patient states that she was taking her normal afternoon nap, and she woke up with a pain in her chest, which radiates to her left arm. When you ask her to describe the pain, she describes it as “an elephant sitting on my chest.” You further question the patient and ascertain that these symptoms started approximately 20 minutes ago; nothing makes the pain better or worse; and the patient describes the pain as 9/10, not quite as bad as her previous heart attacks, but almost. After confirming that the patient has no allergies and takes no medications, per your protocols you administer 324 mg of aspirin orally and 0.4 mg of NTG sublingually.

Recording Time: 1 Minute

Respirations	24 breaths/min
Pulse	74 beats/min
Skin	Warm, dry, and pink
Blood pressure	146/88 mm Hg
Oxygen saturation (SpO ₂)	92% on room air

3. In which medication class is aspirin, and what are the indications and contraindications for administration?
4. What is the mechanism of action of NTG, and what are the indications and contraindications?
5. What are the various routes available to administer NTG?

The first episode of angina is called initial angina. Angina is generally classified as stable or unstable. Stable angina occurs at a relatively predictable frequency, generally occurring with periods of exertion, and is usually relieved by rest and/or medication. Unstable angina occurs without a predictable frequency, often with no precipitating factors, and may or may not be relieved by rest and/or medication. Progressive angina is stable or unstable angina that is accelerating in frequency and duration. Preinfarction angina presents with pain that occurs at rest when the patient is sitting or lying down.

EMS usually becomes involved when stable angina becomes unstable, such as when a patient whose pain is normally relieved by sitting down and taking one NTG tablet has taken three tablets with no relief. Keep in mind that it can be very difficult even for physicians in hospitals to distinguish between the pain of angina and the pain of a myocardial infarction. For this reason, any complaint of chest pain should be treated as a myocardial infarction until proven otherwise.

Of course, not all chest pain is caused by cardiac ischemia or injury. Many other conditions—such as pulmonary embolism, pneumothorax, pneumonia, pericarditis, aortic dissection, indigestion, and peptic ulcer—may cause chest pain that can be mistaken for angina or a myocardial infarction.

Acute Myocardial Infarction

Heart disease is the leading cause of death in the United States.³ Most deaths from AMI are caused by **dysrhythmia** (an irregular or abnormal heart rhythm), usually ventricular fibrillation (VF), which typically occurs during the early hours of the infarct. Dysrhythmias can often be prevented or treated, so *most deaths from AMI are preventable*.

The pain of AMI signals the actual death of cells in the area of the heart where blood flow is obstructed. Once dead, the cells cannot be revived. Instead, they will eventually turn to scar tissue and become a burden to the beating heart. Therefore, fast action is critical in treating a heart attack. The sooner the blockage can be cleared, the fewer the cells that may die. Approximately 30 minutes after blood flow is cut off, some heart muscle cells begin to die. After approximately 2 hours, as many as one-half of the cells in the area can be dead. In many cases, opening the coronary

artery with clot-busting medications, two classes of medications called thrombolytics and fibrinolytics, can prevent or minimize damage to the heart muscle if administered within the first few hours after the onset of symptoms. Angioplasty or percutaneous coronary intervention (PCI), which is the mechanical clearing of the artery, has been shown to be the most effective treatment for a patient experiencing an AMI if performed promptly. Therefore, immediate treatment and transport to an emergency department with cardiac capabilities is essential.

An AMI is more apt to occur in the larger, thick-walled left ventricle, which needs more blood and oxygen, than in the right ventricle.

As with angina, precipitating causes may include atherosclerosis, occlusions, and traumatic or nontraumatic injury. Persistent angina may also be a factor.

Signs and Symptoms of AMI

A patient with an AMI may show any of the following signs and symptoms:

- Sudden onset of weakness, nausea, and sweating without an obvious cause
- Chest pain, discomfort, or pressure that is often crushing or squeezing and that does not change with each breath
- Pain, discomfort, or pressure in the lower jaw, arms, back, abdomen, or neck
- Irregular heartbeat and syncope (fainting)
- Shortness of breath, or dyspnea
- Pink, frothy sputum (indicating possible pulmonary edema)
- Sudden death

The Pain of AMI

The most common symptom of AMI is chest pain. A patient with chronic angina will be aware that something different from previous anginal attacks is happening. The pain of an AMI differs from the pain of angina in three ways:

- It may or may not be caused by exertion but can occur at any time, sometimes when a person is sitting quietly or even sleeping.
- It does not resolve in a few minutes; rather, it can last between 30 minutes and several hours. It also increases in frequency and/or duration.
- It may or may not be relieved by rest or NTG.

The pain of AMI is typically felt just beneath the sternum and is variously described as heavy, squeezing, crushing, or tight. The pain may radiate to the arms (most often the left arm) and into the fingers; it may also radiate to the neck, jaw, upper back, or epigastrium. The pain of AMI is not influenced by coughing, deep breathing, or other body movements.

Not all patients who are having an AMI experience pain or recognize it when it occurs. In fact, approximately one-third of patients never seek medical attention. This can be attributed, in part, to the fact that people are afraid of dying and do not wish to face the possibility that their symptoms may be serious. Middle-aged men are particularly likely to minimize or deny their symptoms. However, a few patients, particularly older people, women, and people with diabetes, do not experience any pain during an AMI but have other common complaints associated with ischemia. This is often referred to as a silent MI because of the lack of pain. These patients may present with symptoms related to a decrease in cardiac output. It is not unusual for sudden dyspnea to develop, progressing rapidly to pulmonary edema, a sudden loss of consciousness, an unexplained drop in blood pressure, an apparent stroke, or simply confusion. Others may feel only mild discomfort and call it indigestion. It is not uncommon for the only complaint, especially in older women, to be fatigue. Heart disease is the number one cause of death of women in the United States in a typical year;⁵ you should consider AMI even when the classic symptom of chest pain is not present. This is also true for older people and people with diabetes.

Words of Wisdom

More men have heart disease, but more women die of heart disease, in part because their symptoms are less clear cut.

Physical Findings of AMI and Cardiac Compromise

The physical findings of AMI vary, depending on the extent and severity of heart muscle damage. The following are common:

- **General appearance.** The patient often appears frightened. There may be nausea, vomiting,

and a cold sweat. The skin is often pale or ashen gray because of poor cardiac output and the loss of perfusion, or blood flow through the tissue. Occasionally, the skin will have a blue tint, called cyanosis; this is the result of poor oxygenation of the circulating blood.

- **Pulse.** Generally, the pulse rate increases as a normal response to pain, stress, fear, or actual injury to the myocardium. Because dysrhythmias are common in an AMI, you may feel an irregularity or even a slowing of the pulse. The pulse may also depend on the area of the heart that has been affected by the AMI. Damage to the inferior area of the heart often presents with bradycardia.
- **Blood pressure.** Blood pressure may fall as a result of diminished cardiac output and diminished capability of the left ventricle to pump. However, most patients with an AMI will have a normal or, most likely, elevated blood pressure.
- **Respiration.** A complaint of difficulty breathing is common with cardiac compromise, so even if the rate seems normal, look at the work of breathing and treat the patient as if respiratory compromise were present, especially in patients with a history of heart failure.
- **Mental status.** Patients with AMIs sometimes experience an almost overwhelming feeling of impending doom. If a patient tells you, “I think I am going to die,” pay attention.

Street Smarts

Place the patient at physical and emotional rest. The stress response triggers a surge of catecholamines (epinephrine and norepinephrine) from the adrenal glands, which, in turn, can send the damaged heart racing. At the same time, the massive discharge throughout the fight-or-flight system puts the peripheral circulation in a state of severe vasoconstriction; thus, not only is the heart being pushed to go faster, but it must also work harder against the escalating afterload. Therefore, the heart's need for oxygen soars precisely when it is already in a state of marked oxygen deprivation. This cycle can lead quickly to dysrhythmias and death.

Begin your care by placing the patient in a position of comfort. From the time you arrive, the patient *must not* expend any effort—not even to walk to the stretcher!

Words of Wisdom

Consequences of AMI

An AMI can have three serious consequences:

- Sudden death
- Cardiogenic shock
- Heart failure

Sudden Death

Many patients with AMI never reach the hospital. Sudden death is usually the result of **cardiac arrest**, in which the heart fails to generate an effective blood flow. Although you cannot feel a pulse in someone experiencing cardiac arrest, there may still be somewhat chaotic electrical activity. The heart is using up energy without pumping. Such an abnormality of heart rhythm is a ventricular dysrhythmia, known as VF.

A variety of other lethal and nonlethal dysrhythmias may follow AMI, usually within the first hour. In most cases, it is premature ventricular contractions (PVCs), or extra beats from the damaged ventricle. Some PVCs by themselves are harmless and are common among healthy people, as well as in sick people. Other dysrhythmias are much more dangerous (**FIGURE 18-8**). These include the following:

- **Tachycardia**. Rapid beating of the heart, greater than 100 beats/min.
- **Bradycardia**. Unusually slow beating of the heart, less than 60 beats/min.
- **Ventricular tachycardia (VT)**. Rapid heart rhythm, usually at a rate of 150 to 200 beats/min. The electrical activity starts in the ventricle instead of the atrium. This rhythm usually does not allow adequate time between beats for the left ventricle to fill with blood. Therefore, the patient's blood pressure may decrease. The patient may also feel weak or light-headed or may even become unresponsive. In some cases, existing chest pain may worsen or chest pain that was not there before onset of the dysrhythmia may develop. The appearance of three or more PVCs in a row is called a "run of VT." Most cases of VT will be more sustained and may deteriorate into VF.

- **Ventricular fibrillation (VF)**. Disorganized, ineffective quivering of the ventricles caused by unorganized electrical activity. No blood is pumped through the body, and the patient usually becomes unresponsive within seconds. The only way to treat this dysrhythmia is to electrically defibrillate the heart. To **defibrillate** means to shock the heart with a specialized electrical current to stop all electrical activity in an attempt to restore a normal, rhythmic beat. By stopping the dysrhythmia, it gives the conduction system the chance to resume its normal activity. Defibrillation is highly successful in saving a life if delivered within 1 to 2 minutes after the onset of VF. If a defibrillator is not immediately available, CPR with high-quality chest compressions must be initiated to buy a few more minutes for arrival of an AED or manual defibrillator. Even if CPR is begun right at the time of collapse, chances of survival diminish each minute until defibrillation is accomplished.

If uncorrected, unstable VT, pulseless VT, or VF will eventually result in **asystole**, the absence of all cardiac electrical and mechanical activity. Without CPR, this may occur within minutes. Because it reflects a long period of ischemia, nearly all patients you find in asystole will die.

Cardiogenic Shock

Shock is a simple concept but one that few people without medical training really understand. The discussion of shock in this chapter is limited to that associated with cardiac problems. Chapter 14, *Shock*, discusses the topic in depth.

For an AEMT, shock is a critical concept. Shock is present when body tissues do not get enough oxygen and nutrients to function normally, causing body organs to malfunction. In **cardiogenic shock**, often caused by a myocardial infarction, the problem is that the heart lacks enough power to force the proper volume of blood through the circulatory system. Cardiogenic shock can occur immediately or as late as 24 hours after the onset of an AMI. The various signs and symptoms of cardiogenic shock are produced by the improper functioning of the body's organs. The challenge for you is to recognize shock in its early stages, when treatment is likely to be more successful.

FIGURE 18-8 Common cardiac dysrhythmias. **A.** Sinus tachycardia. **B.** Sinus bradycardia. **C.** Ventricular tachycardia. **D.** Ventricular fibrillation. **E.** Asystole.

A–C: From *12-Lead ECG: The Art of Interpretation*, Second Edition, courtesy of Tomas B. Garcia, MD; **D and E:** From *Arrhythmia Recognition: The Art of Interpretation*, courtesy of Tomas B. Garcia, MD.

Cardiogenic shock may be differentiated from hypovolemic shock by one or more of the following:

- Chief complaint (chest pain, dyspnea, tachycardia)
- Heart rate (bradycardia or excessive tachycardia)
- Peripheral edema
- Dysrhythmias
- Jugular venous distention
- Crackles (formerly known as rales) on auscultation of breath sounds

A patient with suspected cardiogenic shock should receive the same initial evaluation and treatment as any patient who is reporting chest pain. Pay particular attention to respiratory effort and the presence of peripheral or pulmonary edema. It is imperative to recognize the urgency of transport and to make sure the patient is taken to the closest, most appropriate facility.

Signs and Symptoms of Cardiogenic Shock

One of the first signs of shock is anxiety or restlessness as the brain becomes relatively starved for oxygen. The patient may report “air hunger.” Think of the possibility of shock when the patient is yelling, “I can’t breathe.” Obviously, the patient can breathe because talking would otherwise be impossible. However, the patient’s brain is sensing that it is not getting enough oxygen.

As the shock continues, the body shunts blood to the most important organs, such as the brain and heart, and away from less important organs, such as the skin. Therefore, you may see pale, clammy skin in patients with shock.

As the shock gets worse, the body will attempt to compensate by increasing the amount of blood pumped through the heart. Therefore, the pulse rate will be higher than normal. In severe shock, the heart rate will usually, but not always, be more than 120 beats/min.

Shock can also be characterized by rapid and shallow breathing, nausea and vomiting, and a decrease in body temperature.

Finally, as the heart and other organs begin to malfunction, the blood pressure will fall below normal. A systolic blood pressure of less than 90 mm Hg is easy to recognize, but it is a late finding that indicates decompensated shock. Do not assume that shock is not present just because the blood pressure is normal (compensated shock).

Treatment of Patients With Cardiogenic Shock

Take the following steps when treating patients with signs and symptoms of cardiogenic shock:

1. Position the patient comfortably. Most patients with heart failure will be more comfortable in the semi-Fowler position; however, those with low blood pressure may not tolerate this position. These patients may be more comfortable and more alert in a supine position.
2. Administer oxygen as needed to maintain an SpO_2 of greater than 94%.
3. Assist ventilation as necessary.
4. Cover the patient with sheets or blankets as indicated to preserve body heat. Be sure to cover the patient’s head in cold weather; this is where the most heat is lost.
5. Gain intravenous (IV) access, and give fluid boluses of 250 mL up to a total of 1,000 mL, if necessary, of an isotonic crystalloid solution to achieve a systolic blood pressure of at least 80 mm Hg. Monitor breath sounds for the development of pulmonary edema.
6. Provide prompt transport to the closest, most appropriate emergency department.
7. Call for paramedic backup if available and timely for the administration of vasopressors.

Heart Failure

Failure of the heart occurs when the ventricular myocardium is so damaged that it can no longer keep up with the return flow of blood from the atria.

Heart failure can occur any time after a myocardial infarction, heart valve damage, or long-standing high blood pressure, but it usually happens between the first few hours and the first few days after an AMI.

Left-Side Heart Failure

Just as the pumping function of the left ventricle can be damaged by coronary artery disease, it can also be damaged by diseased heart valves or chronic hypertension. In any of these cases, when the myocardium can no longer contract effectively, the heart tries other ways to maintain an adequate cardiac output. Two specific changes in heart function occur: the heart rate increases, and the left ventricle enlarges to increase the amount of blood pumped each minute.

When these adaptations can no longer make up for the decreased heart function, heart failure eventually develops. Heart failure is commonly

called *congestive* heart failure because the lungs become congested with fluid when the heart fails to pump the blood effectively. Blood tends to back up in the pulmonary veins, increasing the pressure in the capillaries of the lungs. When the pressure in the capillaries exceeds a certain level, fluid (mostly water) passes through the walls of the capillary vessels and into the alveoli. This condition is called pulmonary edema. It may occur suddenly, as in an AMI, or slowly over months, as in chronic heart failure. Sometimes, in patients with an acute onset of heart failure, severe pulmonary edema will develop, in which the patient has pink, frothy sputum and severe dyspnea.

Right-Side Heart Failure

If the right side of the heart is damaged, fluid collects in the body, often showing up as swelling in the feet and legs. The collection of fluid in the part of the body that is closest to the ground is called **dependent edema** (which may be in the sacral area of the back in a bedridden patient). **Pedal edema** is swelling specifically in the feet and lower legs. The swelling causes relatively few symptoms other than discomfort. However, chronic pedal edema may indicate underlying heart disease (right-side heart failure) even in the absence of pain or other symptoms.

Street Smarts

When assessing the patient for peripheral edema, remember that fluid collects in dependent areas. Check the sacral area in patients who are bedridden and the lower extremities in those who are sitting upright.

Signs and Symptoms of Heart Failure

Watch for the following signs and symptoms in a patient you suspect has heart failure:

- **Orthopnea.** The patient finds it easier to breathe when sitting up. When the patient is lying down, more blood is returned to the right ventricle and lungs, causing further pulmonary congestion and shortness of breath.
- Often, the patient is mildly or severely agitated.
- Chest pain may or may not be present.
- The patient often has distended neck veins that do not collapse even when the patient is sitting.

- The patient may have swollen ankles from pedal edema. If the patient is bedridden, the edema may be seen in the sacral area.
- The patient generally will have hypertension, tachycardia, and tachypnea.
- The patient will usually be using accessory breathing muscles of the neck and ribs, reflecting the additional hard work of breathing.
- The fluid surrounding small airways may produce crackles, best heard by listening to either side of the patient's chest, about midway down the back. In severe heart failure, these soft sounds can be heard even at the top (apex) of the lung.
- The patient may have a productive cough, or you may note the presence of pink, frothy sputum.
- The patient may have delayed capillary refill time. With damage to the myocardium, the pumping mechanism is effectively reduced; therefore, there is a lack of perfusion in the extremities, causing delayed capillary refill time.

After heart failure develops, it can be treated but not cured. Regular use of medications may alleviate the symptoms. However, these patients often become ill again and are frequently hospitalized.

Treatment of Heart Failure

Treat a patient with heart failure the same way as a patient with chest pain:

1. Obtain vital signs, monitor heart rhythm, and administer oxygen as needed, ventilating if needed. Continuous positive airway pressure (CPAP) may also be beneficial for patients who meet the requirements. Chapter 11, *Airway Management*, includes more information on CPAP.
2. Allow the patient to remain sitting in an upright position with the legs down.
3. Gain IV access. You may also give fluid if the patient becomes hypotensive. Frequently assess breath sounds for the development of pulmonary edema.
4. Be reassuring; many patients with heart failure are quite anxious because they cannot breathe.
5. Patients who have had problems with heart failure before will usually have specific medications for its treatment. Gather these medications and take them along to the hospital.
6. NTG may be of value if the patient's systolic blood pressure is above 100 mm Hg. If the

patient has been prescribed NTG, and medical control advises you to do so, you can administer it sublingually.

7. Provide prompt transport to the closest, most appropriate emergency department.

Pulmonary Edema

Pulmonary edema is a common complication of myocardial ischemia that may or may not be the result of an AMI. Without treatment, pulmonary edema can result in acute respiratory failure and death. Precipitating causes include heart failure (left-side and/or right-side), myocardial infarction, pulmonary embolism, hypertension, and cardiomegaly (enlarged heart).

Preload and afterload can greatly influence the buildup of pulmonary edema. As the left ventricle loses its ability to pump effectively, blood backs up into the pulmonary veins and, subsequently, into the lungs. This increased pressure causes fluid to leak from the capillaries into the interstitial tissue and the alveoli. This is common in heart failure as the loss of contractile ability results in fluid overload. Pulmonary edema may be acute, as the result of an AMI, or may be chronic, as a result of multiple events or chronic heart failure.

Treatment is focused on maintaining the airway, breathing, and circulation and transporting the patient for definitive care. Obtain a thorough history from the patient, and provide psychological support en route.

Hypertensive Emergencies

Hypertension is defined as any systolic blood pressure of greater than 140 mm Hg or a diastolic blood pressure of greater than 90 mm Hg. Another cardiac-related condition is a hypertensive emergency. A **hypertensive emergency** usually occurs only with a systolic pressure of greater than 180 mm Hg, a rapid increase in the systolic pressure, or a diastolic pressure of 120 mm Hg or greater.⁶ Because blood pressure cannot be directly felt by the patient, the signs and symptoms of a hypertensive emergency are related to the effects of the hypertension. Some patients with chronic hypertension may not experience signs or symptoms until their systolic pressure is substantially higher than this value. One of the most common signs is a sudden severe headache. Often described as “the worst headache

I have ever felt,” this may also be a sign of cerebral hemorrhage. Other signs and symptoms include a strong bounding pulse, ringing in the ears, nausea and vomiting, dizziness, warm skin (dry or moist), nosebleed, altered mental status, and even the sudden development of pulmonary edema. Untreated hypertensive emergencies can result in a stroke or a dissecting aortic aneurysm.

If you suspect your patient is experiencing a hypertensive emergency, attempt to make them comfortable and monitor the blood pressure regularly. Position the patient with the head elevated, transport rapidly to the emergency department, and establish IV access. Call early for paramedic backup if needed for medication administration.

Aortic/Dissecting Aneurysm

An **aortic aneurysm** is a weakness in the wall of the aorta. The aorta dilates at the weakened area, which makes it susceptible to rupture. A **dissecting aneurysm** occurs when the inner layers of the aorta become separated, allowing blood (at high pressures) to flow between the layers. Uncontrolled hypertension is the primary cause of dissecting aortic aneurysms. This separation of layers weakens the wall of the aorta substantially, making it more likely to rupture under conditions of continued high blood pressure. If the aorta ruptures completely, the amount of internal blood loss will be so large that the patient will die almost immediately.

The signs and symptoms of a dissecting thoracic aortic aneurysm include very sudden chest pain located in the anterior part of the chest or in the back between the shoulder blades. It may be difficult to differentiate the chest pain of a dissecting thoracic aortic aneurysm from that of an AMI, but several distinctive features may help. The pain from an AMI is often preceded by other symptoms—nausea, indigestion, weakness, and sweating—and tends to come on gradually, becoming more severe with time and often described as “pressure” rather than “stabbing.” By contrast, the pain of a dissecting aortic aneurysm usually comes on full force from one minute to the next with a description more consistent of “a tearing, burning sensation” originating in the back or scapular area and radiating anteriorly; in some cases, patients describe pain that originates in the anterior chest and radiates posteriorly (**TABLE 18-1**). A patient with a dissecting aortic aneurysm also may exhibit a difference in blood

TABLE 18-1 Acute Myocardial Infarction Versus Dissecting Thoracic Aortic Aneurysm

	Acute Myocardial Infarction	Dissecting Thoracic Aortic Aneurysm
Onset of pain	Gradual, with additional symptoms	Abrupt, without additional symptoms
Quality of pain	Tightness or pressure	Sharp or tearing
Severity of pain	Increases with time	Maximal from onset
Timing of pain	May wax and wane	Does not abate after it has started
Region/radiation	Substernal; back is rarely involved	Back possibly involved, between the shoulder blades
Clinical signs	Peripheral pulses equal	Blood pressure discrepancy between arms or decrease in a femoral or carotid pulse

© Jones & Bartlett Learning.

pressure between the arms or diminished pulses in the lower extremities.

Thoracic aortic aneurysms are almost impossible to diagnose in the prehospital setting, but you must consider them a possibility in any patient with substantial hypertension. Transport the patient without delay.

Patient Assessment

When you are called to a scene where a patient's chief complaint is chest pain, perform a thorough assessment, no matter what the patient says. Any complaint of chest pain or discomfort or other symptoms suggestive of a cardiac etiology is a serious matter.

It is imperative that you recognize a sense of urgency for reperfusion when the patient receives no relief with medications or presents with hypotension or signs of hypoperfusion. Throughout the call, provide emotional support for the patient and an explanation for the family or significant others.

Scene Size-up

While en route to the scene, consider the minimum and maximum standard precautions that will be needed.

Always ensure that the scene is safe for you, your partner, your patient, and bystanders. As you approach the scene, look for and address any hazards, and assess the scene for the potential of violence. Determine how many patients there are. From the nature of the call and first glance at your

patient, consider whether you will need additional resources to assist in moving the patient or patients.

It is important to identify the nature of illness to start your patient assessment on the right track. Use the dispatch information, clues at the scene, and comments of bystanders or family members to begin to develop an idea about the type of problem your patient might be experiencing. For patients with cardiac problems, the clues often include a report of chest pain, difficulty breathing, or sudden loss of consciousness. After you establish a preliminary nature of illness, you will be able to guide your assessment to find the important information much more effectively. Remember not to become fixated on a specific condition at this early point in the assessment; sometimes the situation turns out to be extremely different from how it initially appeared.

Primary Survey

As you approach the patient, form a general impression of the patient's condition to recognize and address life threats. You will likely begin by determining whether the patient is responsive. A decreased level of consciousness may be an indication of decreased perfusion to the brain. In responsive patients, determine if any dizziness or loss of consciousness occurred before EMS arrival.

Perform a rapid full-body scan of the patient. If the patient is not responsive and is not breathing, begin CPR, starting with chest compressions, and call for an AED. An AED should be applied as soon as it is available if the patient is pulseless, not breathing (apneic), and unresponsive. Use of the

AED is discussed in the section on cardiac arrest later in this chapter. Consider calling for paramedic backup if needed and available.

Quickly assess for any major bleeding that needs to be controlled or any substantial edema in dependent areas.

Unless the patient is unresponsive, the airway will most likely be patent. Is there any evidence of debris, blood, or frothy sputum in the airway? Responsive patients should be able to maintain their own airway. Some episodes of cardiac compromise may produce dizziness or even syncopal episodes. If dizziness or fainting has occurred, consider the possibility of injuries from a fall, including potential spinal injuries.

Determine the rate, quality, and degree of distress of respirations. If the rate is too fast or too slow, the depth of respiration seems to be too shallow, or the patient is struggling to breathe, respirations are inadequate. Auscultate breath sounds at this time because these can also be important indicators of patient condition. With cardiac patients, breath sounds may be affected by the presence of fluid buildup. Auscultate for crackles or congestion that indicates pulmonary edema. Some patients feel short of breath even though there are no obvious signs of respiratory distress. Apply oxygen as needed, or if the patient is not breathing or has inadequate breathing, ensure adequate ventilation with a bag-mask device and 100% oxygen to maintain an SpO_2 of greater than 94%.

If available, consider the use of CPAP when needed. For example, patients experiencing pulmonary edema may require positive-pressure ventilation with a bag-mask device or CPAP. CPAP is the most effective way to assist a person with heart failure to breathe effectively and avert the need to use an invasive airway management technique. Be aware of the indications and contraindications of CPAP and be competent in using this equipment.

After assessing airway and breathing, assess the patient's circulation. Determine the rate, rhythm, and quality of the patient's pulse. Is the pulse rhythm regular or irregular? Is the pulse too fast or too slow? Abnormalities in the pulse may indicate substantial problems. It is also important to question patients with an irregular pulse about any past history of dysrhythmias. Assess the patient's skin condition, color, moisture, and temperature, as well as capillary refill time and skin turgor. The patient may present with pallor during the episode, and

diaphoresis is usually present. Assess blood pressure; it may be elevated during the episode and normalize afterward. Also, the patient's temperature may vary. Changes in perfusion may indicate more serious cardiac compromise. Begin treatment for cardiogenic shock early to reduce the workload of the heart. Place the patient in a position of comfort, usually sitting up and well supported.

Make a transport decision based on whether you were able to stabilize life threats during the primary survey. The remainder of the assessment can be performed en route, if time allows. In general, most patients with chest pain should be transported immediately. Whether to use the lights and siren during transport is determined for each patient individually and may be partially based on the estimated transport time. Use lights and siren sparingly when transporting patients with cardiac problems to alleviate some of the stress associated with emergency transport. Little time is saved by using the lights and siren, but you can do a lot to calm your patient and reduce the release of heart-damaging adrenaline through your reassurance and by creating a ride to the hospital that is as nonstressful as possible. Try not to allow the patient to exert himself or herself, strain, or walk.

Transport patients to the closest appropriate facility. If your service is served by one hospital, follow local protocols, and consider alternative destinations when available if the patient would be better served by transport to another facility. This requires that you understand local protocols and any differences in treatment capabilities of various institutions in your area.

History Taking

After you have stabilized life threats, you will want to determine and investigate the chief complaint and the history of the present illness. If the patient is responsive, begin by taking a brief past pertinent history, identifying associated signs and symptoms, and identifying pertinent negatives. If the patient has an altered mental status, friends or family members who are present may have helpful information.

Remember that not all patients experiencing an AMI have the same signs and symptoms. A chief complaint of chest pain or discomfort, shortness of breath, or dizziness should be taken seriously. Many patients who suspect that something

is wrong experience restlessness, appear anxious, and perhaps have a sense of impending doom. Answer questions in a professional manner and provide emotional support. Your professional attitude may be the single most important factor in winning the patient's cooperation and helping the patient through this event. Patients often have a good idea about what is happening, so do not lie and offer false reassurance.

Begin by asking questions about the current situation. Determine whether the patient is experiencing chest pain or discomfort and whether there are any other signs and symptoms. Ask the patient about recurring events along with any increase in frequency and/or duration of an event. Remember that typical angina has a sudden onset of discomfort that is generally of brief duration, lasting only 3 to 5 minutes, not 30 minutes to 2 hours, and is usually relieved by rest and/or medication.

Special Populations

It is important to ask the patient, "How do you feel? Describe it to me." Remember that older patients may not experience pain, only weakness or syncope. Listen for descriptive terms such as pressure, crushing, squeezing, tightness, shortness of breath, dizziness, etc.

Determine whether the patient is having respiratory difficulty; this is common among patients with chest pain. If the patient is experiencing dyspnea, find out whether it is related to exertion and whether it is related to the patient's position. Also determine whether the dyspnea is continuous or if it changes, especially with deep breathing. Note whether the patient has a productive cough. Ask about other signs and symptoms that are commonly found such as nausea and vomiting, fatigue,

Words of Wisdom

Paroxysmal means sudden onset. An episode of paroxysmal nocturnal dyspnea is a sudden onset of shortness of breath at night—usually when a person lies down. This is often the result of heart failure or pulmonary edema.

headache, and palpitations (a feeling of the heart "skipping a beat" or racing). Make sure to ask about any trauma the patient might have experienced during the past few days. Be sure to record your findings, including those that are negative (known as pertinent negatives).

If the patient is responsive, obtain the SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) and ask the following questions specific to a cardiovascular emergency:

- Have you ever had a heart attack?
- Have you been told that you have heart problems?
 - Have you ever been diagnosed with angina, heart failure, or heart valve disease?
 - Have you ever had high blood pressure?
 - Have you ever been diagnosed with an aneurysm?
 - Do you have any respiratory diseases such as emphysema or chronic bronchitis?
- Do you have diabetes, or have you ever had any problems with your blood sugar?
- Have you ever had kidney disease?
- Do you have any risk factors for coronary artery disease, such as smoking, high blood pressure, or high-stress lifestyle?
 - Is there a family history of heart disease?
 - Do you currently take any medications?

The SAMPLE history provides basic information on the patient's overall medical history. The more signs and symptoms a patient has, the easier it is to identify a particular problem. In addition, ask whether the patient has had the same pain before. If so, ask "Do you take any medications for the pain?" and "Do you have any of the medication with you?" Determine whether the patient has taken NTG, aspirin, or any other medications before your arrival. If the patient has had a heart attack or angina before, ask whether the pain is similar.

Words of Wisdom

When you are assessing a patient with a complaint of chest pain or dyspnea, it is common to ask, "How many pillows do you sleep on at night?" Many patients with a history of heart failure will tell you that they sleep on multiple pillows to keep their head up or are unable to sleep lying down and spend their nights in a recliner or similar position. The more upright the patient must sit, the more severe the condition.

Make sure to ask about medication allergies. If the patient is taking medications, determine whether they are prescribed, over-the-counter, or herbal medications, as well as for what condition they are taken, and/or if there is any recreational drug use. Even when a patient may not be able to articulate the exact medical condition, knowing the patient's medications may give you important clues. For example, a patient may say he has "heart problems." You see that he is taking furosemide (Lasix), digoxin, and amiodarone (Cordarone). Furosemide is a diuretic, digoxin increases the strength of heart contractions, and amiodarone controls certain types of dysrhythmias. These drugs are often prescribed together for patients with heart failure and may alert you to carefully evaluate the lungs for the presence of crackles, which indicate fluid in the lungs and a need to increase the amount of oxygen being delivered. Ask about any other medical conditions the patient may have. Asking about the last oral intake may seem unnecessary, but this information can be very important; it is always better to have too much information

rather than not enough. Also remember to ask about any home remedies the patient might have used.

Be sure to include the OPQRST-I questions (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions) when you are obtaining the symptoms as part of the SAMPLE history. Using OPQRST-I helps you to understand the details of specific complaints, such as chest pain (TABLE 18-2). Ask whether the patient has taken anything for the pain and, if so, whether it helped. If the patient reports having taken NTG without relief, it is important to establish *why* the patient did not obtain relief.

Street Smarts

When questioning a patient about medications, remember to ask about the use of herbal remedies or home remedies. Most patients do not consider these substances to be medications or realize that they can interact with prescribed medications.

TABLE 18-2 OPQRST-I Mnemonic for Assessing Pain	
Onset	When did the problem begin, and what does the patient think may have caused it?
Provocation/palliation	Ask what makes the pain or discomfort better or worse. Is it positional? Does a deep breath or palpation of the chest make it worse? Did the patient take anything for it (including anything nonprescribed)?
Quality	Ask the patient to describe the pain. Let the patient choose the words to describe what is happening. If the patient is unable to describe the pain, try to avoid supplying the patient with only one option. Do not ask, "Does it feel like an elephant is sitting on your chest?" Instead, say, "Tell me what the pain feels like." If the patient cannot answer an open-ended question, then provide a list of alternatives: "There are lots of different kinds of pain. Is your pain more like a heaviness, pressure, burning, tearing, dull ache, stabbing, crampy, or needlelike?"
Region/radiation	Ask where the pain or discomfort is located and whether it has spread to another part of the body.
Severity	Ask the patient to rate the pain on a simple scale. Often, a scale ranging from 0 to 10 is used, in which 0 represents no pain at all and 10 represents the worst pain imaginable. Do not use the patient's answer to determine whether the pain has a serious cause. Instead, use this scale to determine whether the pain is getting better or worse. After a few minutes of oxygen or administration of NTG, ask the patient to rate the pain again.
Time	Find out how long the pain has been going on, how long it lasts when it is present, and whether it has been intermittent or continuous. Ask whether it is worsening or improving and if it is associated with rest or activity.
Intervention	Ask what has been done prior to EMS arrival. Has the patient taken prescribed NTG or other medication? If so, when? How many? Has there been any change?

Abbreviations: EMS, emergency medical services; NTG, nitroglycerin
© Jones & Bartlett Learning.

At least two reasons might explain this failure. One possibility is that the patient is, indeed, having an AMI, for which NTG would not provide complete pain relief. The other possibility is that the NTG has simply gone stale. To retain its potency, NTG must be stored in a dark, airtight container; if it is left out in the open for any period (for example, if the patient stores the medicine on the windowsill above the kitchen sink), it loses its therapeutic effectiveness. To distinguish between the two explanations, ask the patient whether the usual effects of NTG occurred. NTG tablets that are therapeutically active may cause a slight burning under the tongue, may make the patient feel flushed, or may give the patient a transient throbbing headache. If the patient confirms one of those effects but the chest pain still would not go away, then you know there was most likely nothing wrong with the NTG but there may be something very wrong with the patient. A third possibility is that the patient's symptoms are not related to a cardiac problem.

Secondary Assessment

Circumstances will determine which aspects of the physical examination will be used. A physical

examination of a patient with chest pain would typically focus primarily on the cardiovascular system. Evaluate the patient's circulation by assessing pulses at various locations, and assess skin color, temperature, and condition. Is the skin cool or moist? How do the mucous membranes look? Are they pink, ashen, or cyanotic? Are the pulses of equal strength bilaterally? Does the patient have any edema in the extremities, especially the lower extremities? All of these physical findings can help identify poor circulation, which may be caused by a failure of the cardiovascular system.

In addition to the cardiovascular system, examine the respiratory system for signs of inadequate ventilation. These two systems are closely related, and some problems with the respiratory system can be caused by cardiovascular issues. Auscultate breath sounds for depth, equality, and any adventitious sounds such as crackles or wheezing. Listen for gurgling, and look for blood-tinged or foamy froth from the mouth and/or nose. Wet-sounding lungs indicate fluid is being moved into the lungs from the circulatory system, possibly because of a problem with the heart. Are the breath sounds equal? Are the neck veins distended? Is the trachea deviated, or is it midline? The answers to these questions can help determine whether a problem

YOU are the Provider

Part 3

As soon as the medications have been administered, you assist the patient onto the stretcher, secure her, and place her in the back of the ambulance. She states that her pain now rates about 2 out of 10, and the pressure has greatly diminished. You direct your partner to repeat the patient's vital signs while you prepare to obtain IV access. The patient states that although she has an extensive cardiac history, she really does not like needles, and asks if it is necessary for you to stick her.

Recording Time: 10 Minutes

Respirations	20 breaths/min
Pulse	68 beats/min, regular
Skin	Warm, dry, and pink
Blood pressure	122/84 mm Hg
Oxygen saturation (SpO ₂)	96% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

6. Does this patient require IV access?
7. Should paramedic backup be requested for this patient?

exists with the lungs or with the heart. Although the physical examination is not usually as important as the history in a patient with a possible cardiac problem, it may produce important clues to the patient's condition.

Reassess the level of consciousness. Is the patient diaphoretic? Is there nausea or vomiting, fatigue, or palpitations? Note the presence of edema in the extremities or sacral area. Has the patient had a headache or a syncopal episode? Has the patient's behavior changed? Note any anguished facial expressions or activity limitations. Inspect the neck, looking at the position of the trachea and the appearance of the neck veins. Palpate for any areas of crepitus or tenderness in the thorax and any pulsation or distention in the epigastrium.

Measure and record the patient's vital signs, including pulse, respirations, and blood pressure. You must obtain readings for systolic and diastolic blood pressures. If available, use pulse oximetry. Pulse oximetry may not give an accurate measurement if the patient has poor circulation, has been exposed to a toxic chemical, or is in cardiac arrest, but it should be used and the readings noted for all patients with possible cardiac problems. Assess blood glucose levels.

If you suspect stroke or aortic aneurysm, obtain blood pressure readings in both arms and compare the measurements. Conditions such as these may cause the blood pressure to vary from the left to the right. Markedly elevated pressures may also contribute to stroke, aortic dissection, or heart failure. A normal pulse pressure is 30 to 40 mm Hg. If the pulse pressure is narrowed (below 30 mm Hg), the patient may be tachycardic or experiencing a cardiac tamponade. If the pulse pressure is widened (above 40 mm Hg), the patient may be in late shock.

Repeatedly obtain the vital signs at appropriate intervals. Be sure to note the time that each set of vital signs is obtained.

Reassessment

Repeat the primary survey by checking to see whether the patient's chief complaint and condition have improved or are deteriorating. Vital signs should be reassessed at least every 5 minutes or any time substantial changes in the patient's condition occur. It is essential to monitor the patient with a

Assessment Pearls

- Bring the stretcher to the patient. DO NOT walk the patient to the stretcher!
- Utilize CPAP for those patients with dyspnea and pulmonary edema who are alert and able to follow commands.
- ALWAYS check blood pressure prior to administration of NTG.
- Geriatric patients do not always have associated pain with an AMI. Consider any episode of syncope or weakness to be cardiac related and provide rapid treatment and transport.
- Remove any medication patches found on the patient, particularly those who are unresponsive, hypotensive, or in cardiac arrest. The medication may be the cause.
- Take the AED in your jump bag for patients with a complaint of chest pain. This will greatly reduce the time to the first shock if the patient goes into cardiac arrest and increase the chance of survival.
- Administer IV fluid judiciously in patients complaining of chest pain. While boluses of fluid may increase blood pressure in a hypotensive patient, they also increase the workload on what may be an already damaged myocardium.
- If a 12-lead electrocardiogram (ECG) is obtained, leave the leads attached so that you do not have to reattach them for another tracing.

suspected AMI closely because sudden cardiac arrest is always a risk. If cardiac arrest occurs, you must be ready to begin automated defibrillation or chest compressions immediately. If an AED is immediately available, use it; if not, perform CPR until the AED is available, as discussed in the later section on cardiac arrest. Reassess your interventions to see whether they are helping and whether the patient's condition is improving. Reassessment will also determine whether further interventions are indicated or contraindicated.

Provide prompt transport to the closest appropriate facility so that treatments such as clot-busting medications or angioplasty can be initiated. To be most effective, these treatments must be started as soon as possible after the onset of the attack. Alert the emergency department about the status of your patient and your estimated time of arrival. Do not delay transport to assist with administration of NTG. The medication can be given en route.

Report to the hospital by radio or cellular telephone while en route. Include information about the patient's history, vital signs, the reassessment of vital signs, medications taken, and any treatment you are giving. Follow the instructions of medical control. Describe the patient's condition to the emergency department staff on arrival.

It is important to document your assessment of the patient. You must record the interventions performed. All interventions should be initiated according to protocol. If the intervention required an order from medical control, document the intervention and/or medication requested and whether approval was granted. It must be clear in your documentation that the patient was reassessed appropriately following any intervention. The patient's response to the intervention and the time of each intervention must also be recorded.

Emergency Medical Care for Chest Pain or Discomfort

Your treatment of the patient begins with proper positioning. As mentioned before, some patients will not tolerate being positioned supine, so they should be allowed to sit up (leaning back on the stretcher). Also, loosen tight clothing to make the patient as comfortable as possible.

Provide oxygen as needed and maintain SpO₂ at 94% or higher. For patients with mild dyspnea, a nasal cannula may be all that is needed, whereas patients with more serious respiratory difficulty will respond better to a nonbreathing mask. A patient who is unresponsive or in obvious respiratory distress may need assistance with breathing. Use a bag-mask device or a positive-pressure ventilation device such as positive end-expiratory pressure, CPAP,

Special Populations

Cardiovascular emergencies are relatively rare in children. When such problems arise, they are often related to volume or infection rather than a primary cardiac cause, unless the child has congenital heart disease. The primary survey can help you quickly identify a cardiovascular emergency, understand the likely cause, and institute potentially life-saving treatment. Call early for paramedic backup if a need is suspected.

The child's appearance gives an overview of perfusion, oxygenation, ventilation, and neurologic status. For a suspected cardiovascular problem, an abnormal appearance may indicate inadequate brain perfusion and the need for rapid intervention.

Tachypnea, without retractions or abnormal airway sounds, is common in an infant or child with a primary cardiac problem; it is a mechanism for blowing off carbon dioxide to compensate for metabolic acidosis related to poor perfusion. In contrast, when cardiac compromise progresses to heart failure, pulmonary edema results in increased work of breathing and a fast respiratory rate. The presence of pallor, cyanosis, or mottling may tip you off to this problem.

Bradycardia in children is most often a result of hypoxia, rather than of a primary cardiac problem (such as heart block). Airway management, supplemental oxygen, and assisted ventilation as needed are always first-line treatment. Also, treat any underlying respiratory problem. Less-common causes of bradycardia include congenital or acquired heart block and toxic ingestion of beta-blockers, calcium channel blockers, or digoxin. Elevated intracranial pressure can also cause bradycardia and should be considered in children with ventricular shunts, a history of head injury, or suspected child abuse without a consistent injury history.

Tachycardia, a pulse rate higher than normal for the patient's age, is common in children. Although it may be a sign of serious underlying illness or injury, it may also be caused by fever, pain, or anxiety. Interpret the presence of tachycardia in the context of the remainder of the primary survey. For example, if a child appears well but has a fever, tachycardia is likely and treatment with antipyretics is all that is necessary. If a tachycardic child has a history of copious vomiting or diarrhea, fluid resuscitation is the appropriate treatment.

For suspected cardiovascular compromise, start with airway and breathing, and provide supportive care as needed. Ensure adequate oxygenation and ventilation, and then assess the circulation by checking heart rate; pulse quality; skin condition, color, moisture, and temperature; and blood pressure when possible. Use information from the primary survey to make an initial decision about the likely underlying cause, the patient's priority, and the need for immediate treatment or transport.

If you determine that the patient's condition is stable enough for you to continue the assessment on site, continue with the SAMPLE history and the secondary assessment. Repeat the primary survey after each intervention, and monitor trends over time.

bilevel positive airway pressure, or, if an advanced airway is in place, a manual or automatic transport ventilator if available and you have been approved to use one of these methods in your service.

If available, obtain a 12-lead ECG within 10 minutes of patient contact. Another crew member can use this time to establish vascular access. One of the most important components in the rapid identification and treatment of a cardiac event is rapid acquisition of the 12-lead ECG. Always perform a 12-lead ECG (where available) *before* administering any medication (except possibly aspirin and oxygen). Repeat the 12-lead ECG with each set of vital signs, when symptoms change, and as often as necessary. This is important because the patient's ECG may be normal between episodes of discomfort, but show signs of ischemia, injury, or infarction during episodes of discomfort.

If not done previously, gain IV access as long as it does not cause a delay in transport. A saline lock is sufficient unless the patient is hypotensive. If so, consider a 250-mL bolus of an isotonic crystalloid solution such as normal saline.

Words of Wisdom

ST-segment elevation myocardial infarction (STEMI) treatment involves rapid reperfusion of the affected lesion or lesions. *Reperfusion therapy* refers to restoration of blood flow, either by procedural means (such as PCI) or by administering a fibrinolytic medication to dissolve blood clots (pharmacologic reperfusion). You should know which medical facilities in your area are equipped to administer **fibrinolytic therapy** and/or PCI.

Depending on local protocol, prepare to administer aspirin and assist with prescribed NTG. Aspirin (acetylsalicylic acid) prevents clots from forming or getting bigger. Administer aspirin according to local protocol. Low-dose aspirin comes in 81-mg chewable tablets. The recommended dose is 162 mg (two tablets) to 324 mg (four tablets). Be sure you have verified that the patient is not allergic to aspirin before you give it, because many people are. Also, ask the patient about any history of internal bleeding such as stomach ulcers; if so, contact medical control before giving the patient aspirin.

NTG relieves the pain of angina by increasing the size of the vessels to increase oxygenation to

the hypoxic tissue. NTG comes in several forms—as a small white pill, placed sublingually (under the tongue); as a spray, also taken sublingually; and as a skin patch applied to the chest. In any form, the effect is the same. NTG relaxes the muscle of blood vessel walls, dilates coronary arteries, increases blood flow and the supply of oxygen to the heart muscle, and decreases the workload of the heart. NTG also dilates blood vessels in other parts of the body and can sometimes cause low blood pressure and/or a severe headache. Other side effects include changes in the patient's pulse rate, including tachycardia or bradycardia. For this reason, you should take the patient's blood pressure within 5 minutes after each dose. If the systolic blood pressure is less than 100 mm Hg, do not give more NTG. Other contraindications include the presence of a head injury, use of erectile dysfunction drugs within the previous 24 to 72 hours, and the maximum prescribed dose has already been given (usually three doses). Nitrous oxide may also provide a measure of pain relief. Follow local protocols for administration.

Administering Nitroglycerin

Check the condition of the medication and its expiration date. Be sure to wear gloves when handling NTG tablets or spray because it is easily absorbed through the skin. If the patient has an NTG patch on when you arrive, be sure to carefully remove it if the patient is hypotensive or in cardiac arrest (before use of an AED).

Words of Wisdom

Allowing a patient with a dry mouth to rinse the mouth with water prior to administration of NTG will help the tablet dissolve faster. Make sure the patient does not swallow the water. This is not necessary when using the spray form of NTG.

After you obtain permission from medical control, administer prescribed NTG to the patient. NTG works in most patients within 5 minutes. Most patients who have been prescribed NTG carry a supply with them. Patients take one dose of NTG under the tongue whenever they have an episode of angina that does not immediately go away with rest. If the pain is still present after 5 minutes, patients are typically instructed by their physicians to take two

subsequent doses as needed, up to a total of three doses. Follow local protocols for administration of additional doses of NTG.

Be aware that NTG will lose its potency over time, especially if exposed to light and air. Patients who take it only rarely may keep a bottle in their pocket for months. It may lose its potency even before its expiration date.

To safely assist the patient with NTG, follow the steps listed in **SKILL DRILL 18-1**.

Heart Surgeries and Cardiac Assistive Devices

During the past 40 years, hundreds of thousands of open-heart procedures have been performed to bypass damaged segments of coronary arteries in the heart. In a coronary artery bypass graft, a blood vessel from the chest or leg is sewn directly from the

aorta to a coronary artery beyond the point of the obstruction. Another procedure is percutaneous transluminal coronary angioplasty, which aims to dilate, rather than bypass, the coronary artery. In this procedure, usually called an angioplasty or balloon angioplasty, a tiny balloon is attached to the end of a long, thin tube. The tube is introduced through the skin into a large vein, usually in the groin, and then threaded into the narrowed coronary artery, with radiographs serving as a guide. After the balloon is in position inside the coronary artery, it is inflated. The balloon is then deflated, and the tube is removed from the body. Sometimes, a metal mesh called a stent is placed inside the artery instead of or after the balloon. The stent is left in place permanently to help keep the artery from narrowing again.

A patient who has experienced an AMI or angina will almost certainly have undergone one of

Skill Drill 18-1 Administering Nitroglycerin

Step 1

Obtain an order from medical control—online or off-line protocol. Take the patient's blood pressure. Administer NTG only if the systolic blood pressure is greater than 100 mm Hg.

Attempt IV access prior to administration of NTG in patients who have not received it previously or who are known to respond to NTG with hypotension. If the patient has a prescription for NTG and you are assisting them with their own medication, an IV line should not be necessary first.

Step 2

Check that you have the right medication, the right patient, and the right delivery route. Check the expiration date. Make sure the patient has no contraindications, such as having taken a medication for erectile dysfunction in the past 24 to 72 hours.

Ask the patient about the last dose taken and its effects. Make sure that the patient understands the route of administration. Be prepared to have the patient lie down to prevent fainting if the NTG substantially lowers the patient's blood pressure (the patient gets dizzy or feels faint).

(continues)

Skill Drill 18-1 Administering Nitroglycerin (continued)

Step 3

Ask the patient to lift the tongue. Place the tablet or spray the dose under the tongue (while wearing gloves), or have the patient do so. Have the patient keep the mouth closed with the tablet or spray under the tongue until it is dissolved and absorbed. Caution the patient against chewing or swallowing the tablet.

© Jones & Bartlett Learning.

Step 4

Recheck the blood pressure within 5 minutes. Record the medication and the time of administration. Reevaluate the chest pain and blood pressure, and note the response to the medication. If the chest pain persists and the patient still has a systolic blood pressure of greater than 100 mm Hg, repeat the dose every 5 minutes as authorized by medical control. In general, a maximum of three doses of NTG is given for any one episode of chest pain. If protocols allow, consider administering 162 to 324 mg of aspirin.

these procedures. Patients who have undergone a bypass graft will have a long surgical scar on their chest from the procedure (**FIGURE 18-9**). Patients who have undergone an angioplasty or coronary artery stent usually will not. However, newer “key-hole” surgical techniques may not produce a large scar. You should not assume that a patient who has a small scar has not had bypass surgery. Chest pain in a patient who has undergone any of these procedures should be treated the same as chest pain in patients who have not undergone any heart surgery. Perform all the described tasks, and transport the patient promptly to the emergency department of the closest, most appropriate hospital. If CPR is required, begin with compressions and perform the procedure in the usual way, regardless of the scar on the patient’s chest. Similarly, if indicated, an AED should be used as soon as possible.

FIGURE 18-9 A long vertical surgical scar on a patient’s chest suggests previous coronary artery bypass graft surgery.

Many people with heart disease in the United States have cardiac pacemakers to maintain a regular cardiac rhythm and rate (**FIGURE 18-10**). Pacemakers are inserted when the electrical conduction system of the heart is so damaged that it cannot function properly. These battery-powered devices deliver an electrical impulse through wires that are in direct contact with the myocardium. The generating unit is generally placed under a heavy muscle or a fold of skin; it typically resembles a small silver dollar under the skin in the left upper part of the chest.

Normally, you do not need to be concerned about problems with pacemakers. Thanks to modern technology, an implanted unit will not require replacement for years. Wires are well protected and rarely broken. Previously, pacemakers sometimes malfunctioned when a patient got too close to an electrical radiation source, such as a microwave oven, but this is no longer the case. Every patient with a pacemaker still should be aware of the precautions, if any, which must be taken to maintain its proper functioning.

If a pacemaker does not function properly, as when the battery wears out, the patient may experience syncope, dizziness, or weakness because of an excessively slow heart rate. The pulse ordinarily will be less than 60 beats/min because the heart is beating without the stimulus of the pacemaker and

without the regulation of its own electrical conduction system, which may be damaged. In these circumstances, the heart tends to assume a fixed slow rate that is not fast enough to allow the patient to function normally. A patient with a malfunctioning pacemaker should be promptly transported to the emergency department for evaluation and possible repair of the pacemaker. When an AED is used, the patches should not be placed directly over the pacemaker. This will ensure a better flow of electricity through the patient's body.

Automatic Implantable Cardiac Defibrillators

More and more patients who survive cardiac arrest due to VF have a small automatic implantable cardiac defibrillator (AICD) implanted (**FIGURE 18-11**). Some patients who are at particularly high risk for a cardiac arrest have them as well. These devices are attached directly to the heart and can prolong lives. They continuously monitor the heart rhythm, delivering shocks as needed. Regardless of whether a patient having an AMI has an AICD, the patient should be treated like all other AMI patients. Treatment should include performing CPR, beginning with compressions, and using an AED if the patient goes into cardiac arrest. Generally, the electricity from an

FIGURE 18-10 A pacemaker, which is typically inserted under the skin in the left upper part of the chest, delivers an electrical impulse to regulate the heartbeat.

© Carolina K. Smith, MD/Shutterstock.

FIGURE 18-11 An automatic implantable cardiac defibrillator (AICD) is attached directly to the heart and continuously monitors heart rhythm, delivering shocks as needed. The electricity from the AICD is so low that it has no effect on rescuers.

© Andrew Pollak, MD. Used with permission.

AICD is so low that it will have no effect on rescuers and, therefore, should not be of concern to you.

External Defibrillator Vest

An alternative to the AICD is the external defibrillator vest. This device is a vest with built-in monitoring electrodes and defibrillation pads, which is worn under the patient's clothing. The vest is attached to a monitor worn on a belt or hung from a shoulder strap. The monitor provides alerts and voice prompts when it recognizes a dangerous rhythm and before a shock is delivered. Unlike the implantable defibrillator, this device uses high-energy shocks similar to an AED, so you should avoid contact with the patient if the device warns that it is about to deliver a shock. Blue gel under the large defibrillation pads indicates that the device has already delivered at least one shock.

If the patient is in cardiac arrest, the vest should remain in place while CPR is being performed unless it interferes with compressions. If it is necessary to remove the vest, simply remove the battery from the monitor and then remove the vest. You can then use your own AED on the patient. Any patient who is wearing a device that has already delivered a shock should be transported to the hospital for further evaluation.

Left Ventricular Assist Devices

Left ventricular assist devices (LVADs) are used to enhance the pumping of one or both ventricles in patients with severe heart failure or in patients who need a temporary boost due to a myocardial infarction. They are also used as a bridge to heart transplantation while a donor heart is being located, or as a permanent solution for patients who do not qualify for a transplant. LVADs provide a bypass for a left ventricle that is unable to meet the needs of the body. In addition to the multiple LVAD devices available for adult patients with heart failure, there is one approved LVAD designed for children aged 5 to 16 years.

There are several types of LVADs; the most common ones have an internal pump unit and an external battery pack. Because LVADs provide a continuous instead of a pulsatile flow, it may be difficult to palpate a pulse. In such cases, assess perfusion by noting the level of consciousness; skin color, temperature, and moisture; and glucose level. Blood pressure is best determined by use of a Doppler and is often unobtainable in the field.

Auscultate the chest for a “hum” that indicates the device is working. If no “hum” is heard, but the patient shows signs of circulation, take the following steps to troubleshoot possible equipment failure:

- If the device has a display screen, look for an alarm code.
- Check cables to ensure everything is connected.
- Check power supply. The patient should have extra batteries. Replace only *one* battery at a time.
- Call the manufacturer's 800 number for assistance.

If you encounter a patient with an LVAD, you will primarily provide support measures and basic care while using the caregiver as a resource during transport. These patients should have a “go bag” that must always be transported with them. Risk factors associated with the implantation of an LVAD include excessive bleeding following the operation, infection, blood clots leading to strokes, and acute heart failure. LVAD patients are on chronic anticoagulant medications and over time may develop a bleeding disorder similar to hemophilia—basically an acquired von Willebrand deficiency. Additional concerns include epistaxis, gastrointestinal bleeds, and intracranial hemorrhage.

Although medical equipment failure is rare in these cases, be prepared to provide CPR if the situation arises. Keep in mind that the LVAD may be functioning in the absence of a palpable pulse. If you encounter a patient with this device, then contact medical control or follow your local protocols. Understand that chest compressions could dislodge the device or its connections, leaving a hole in the heart, and should be avoided if possible. Medical control may order abdominal compressions for these patients as an alternative. Notify paramedics as soon as possible so that other supportive measures may be initiated.

Street Smarts

The manufacturers of special equipment such as an LVAD often include an 800 number to call for information specific to patient care. Patients and family members typically carry identification cards with necessary phone numbers and may be able to share this information with you.

Cardiac Arrest

Cardiac arrest is the complete cessation of functional cardiac activity—either electrical, mechanical, or both. It is indicated in the field by the absence of a carotid pulse. Cardiac arrest may be the result of trauma or numerous medical conditions, such as end-stage renal disease, hyperkalemia with renal disease, or hypothermia, to name a few.

Automated External Defibrillation

In the late 1970s and early 1980s, scientists developed a small computer that could analyze electrical signals from the heart and determine when VF was taking place. This development, along with improved battery technology, made possible the portable automated defibrillator, which can automatically administer an electrical shock to the heart when needed.

The AED machines come in models with different features (**FIGURE 18-12**). All of them require a certain degree of operator interaction, beginning with applying the pads and turning the machine on. The operator also has to push a button to deliver an electrical shock, depending on the model. Many AEDs use a computer voice synthesizer to advise the operator what steps to take on the basis of the AED's analysis. Some have a button that tells the computer to analyze the heart's electrical rhythm; other models start doing this as soon as they are turned on. Although most defibrillators are now semi-automated, the acronym AED is used as the general term to describe all of these machines. Fully automated AEDs were among the first AEDs made; however, unlike the semiautomated AED, they delivered the shock automatically (the operator had no control over when the shock was delivered). Because of the safety concerns, few, if any, fully automated AEDs remain in use; all manufacturers now produce only semiautomated external defibrillators.

AEDs also come equipped to administer a monophasic shock or a biphasic shock. Monophasic means to send the energy in one direction, from negative to positive, and biphasic means to send the energy in two directions simultaneously. The advantage of biphasic shock is that it produces a more efficient defibrillation and may require a lower energy setting. The initial and subsequent energy setting for VF and pulseless VT on a monophasic machine is 360 joules. With the biphasic technology, the energy can be 120 joules for the first and all subsequent shocks

FIGURE 18-12 Automated external defibrillators vary in their design, features, and operation. Two devices are shown here.

Upper: © Photographee.eu/Shutterstock; Lower: © Jones & Bartlett Learning.

or can start at 120 joules and then escalate to 200 joules for subsequent shocks. The optimum energy setting for biphasic AEDs is still being studied, and no recommendation is currently supported in the literature. Most AEDs currently in use are biphasic.

The computer inside the AED is programmed to recognize rhythms that require defibrillation to correct, most commonly VF and pulseless VT. The current programs are extremely accurate. It would be rare for an AED to recommend a shock when a shock would not be indicated, and an AED rarely fails to recommend one when it would be indicated. Therefore, if the AED recommends a shock, you can believe it is indicated.

The AED provides several advantages. First, the machine is fast, and delivers the most important treatment for the patient in VF or pulseless VT: an electrical shock. It can be delivered within 1 minute of your arrival at the patient's side. Second, AEDs

are easy to operate. Paramedics do not have to be on the scene to provide this critical intervention.

Current AEDs offer two other advantages. The shock can be given through remote, adhesive defibrillator pads, which are safe to use. Also, the pad area is larger than manual paddles, which means that the transmission of electricity is more efficient. Usually, there are pictures on the pads to remind you where they are placed on the patient's chest. As a safety measure, make sure the patient is not lying on wet ground or touching metal objects when a shock is being administered.

Not all patients in cardiac arrest require an electrical shock. Although all patients in cardiac arrest should be analyzed with an AED, some do not have shockable rhythms (eg, pulseless electrical activity and asystole). Asystole (flatline) indicates that no

electrical or mechanical activity is present, whereas pulseless electrical activity usually refers to a state of cardiac arrest despite an organized cardiac rhythm. In both cases, CPR should be initiated as soon as possible, beginning with chest compressions.

Rationale for Early Defibrillation

Few patients who experience sudden cardiac arrest outside of a hospital survive unless a rapid sequence of events takes place. The chain of survival is a way of describing the ideal sequence of events that should take place when such an arrest occurs.

The six links in the chain of survival are as follows (**FIGURE 18-13**):

- Recognition of early warning signs and immediate activation of EMS

YOU are the Provider

Part 4

After you establish IV access, you contact your dispatch on the radio to request a paramedic intercept. You are advised that no paramedic units are available and you will have to transport this patient on your own. You inform your partner to transport emergent to First Care Hospital, which is approximately 22 minutes away. Your partner asks why you are bypassing Unity Hospital, which is only 10 minutes away, to which you reply that Unity does not have a cardiac catheterization laboratory, and First Care does, and according to local protocols, any patient suspected of having an AMI is to be diverted to the closest facility with a catheterization lab. You contact First Care, and inform them that you are coming in with a "heart alert" and you relay your findings. You continue to monitor your patient, and when asked, she states that her pain is increasing back up to a 7 out of 10. Per your protocols, you administer a second 0.4-mg dose of NTG sublingually. After approximately 90 seconds, the patient appears to become unresponsive. You quickly palpate a carotid pulse, and finding none, begin chest compressions while attaching the AED electrodes to the patient. Your partner stops the ambulance to allow the AED to analyze. On receiving the message "Shock advised," you defibrillate the patient and immediately after the shock restart chest compressions. You inform your partner of the need to divert to Unity Hospital and ask him to contact both facilities and advise them of the change in the patient's status. Your partner advises that you are approximately 2 minutes from Unity Hospital. With the relatively short ETA, you elect to withhold insertion of an advanced airway and continue ventilations with a bag-mask device. On arrival at Unity Hospital, you continue CPR while the patient is wheeled into the resuscitation bay, at which point you turn over care to the awaiting physician while hospital staff take over CPR.

Recording Time: 20 Minutes

8. What is the most common error with AED operation?
9. What are the six links in the chain of survival?

FIGURE 18-13 The six links in the out-of-hospital chain of survival.

© Jones & Bartlett Learning. Data from American Heart Association.

- Immediate CPR with emphasis on high-quality chest compressions
- Rapid defibrillation
- Basic and advanced EMS care
- ALS and postarrest care
- Recovery

If any one of the links in the chain is absent or delayed, the patient's chances for survival diminish. For example, few patients benefit from defibrillation when more than 10 minutes elapse before administration of the first shock or if CPR is not performed in the first 2 to 3 minutes. If all links in the chain are strong, the patient has the best possible chance of survival. The link that is the greatest determinant for survival is the third link—rapid defibrillation.

CPR helps patients in cardiac arrest because it maintains myocardial and cerebral perfusion, thus prolonging the period during which defibrillation can be effective. Rapid defibrillation has successfully resuscitated many patients with cardiac arrest from VF. However, defibrillation works best if it takes place within 2 minutes of the onset of the cardiac arrest. To try to achieve better survival rates among cardiac arrest victims, many communities are exploring the idea that nontraditional first responders should be trained to administer early defibrillation. These responders would include police officers, security personnel, lifeguards, maintenance workers, and flight attendants. As an AEMT, you should support these efforts to shorten the time until defibrillation. Remember, seconds really matter when the patient is in cardiac arrest.

The fifth step in the chain of survival is ALS and postarrest care. This refers to controlling temperature to optimize neurologic recovery in the field and maintaining glucose levels in the patient who

is hypoglycemic. Ventilations should be delivered at less than 12 breaths/min or as needed to achieve an end-tidal carbon dioxide level of 35 to 45 mm Hg, maintain oxygen saturation between 94% and 99%, and ensure blood pressure is higher than 90 mm Hg. It also includes cardiopulmonary and neurologic support at the hospital, PCIs when indicated, and an electroencephalogram to detect seizure activity.

The final step in the chain of survival is recovery. CPR guidelines have been expanded to include health disparities, management of opioid-related emergencies, and physical and emotional recovery for the patient and family.

Integrating the AED and CPR

Because most cardiac arrests occur in the home, a bystander at the scene may already have started CPR before you arrive. For this reason, you must know how to work the AED into the CPR sequence. Remember that the AED is not very complex; it may not be able to distinguish other movements from VF. Therefore, do not touch the patient while the AED is analyzing the heart rhythm and delivering shocks. Stop CPR, and let the AED do its job.

AED Maintenance

It is crucial at the beginning of your shift to ensure that you have a functioning AED. You must become familiar with the maintenance procedures required for the brand of AED your service uses. Read the operator's manual. If your defibrillator does not work on the scene, someone will want to know what went wrong. That person may be your system's administrator, your medical director, the local newspaper reporter, or the family's attorney. You will be asked to show proof that you

maintained the defibrillator properly and attended any mandatory in-service sessions.

When an error occurs, it is usually because of one of the following:

- **Failure to charge or maintain the AED.** The most common error is not having a charged battery. To avoid this problem, many defibrillator companies have built smarter machines that will warn the operator that the battery is unlikely to work. However, some of the older models do not have this feature.
- **Failure to use the AED correctly.** Another form of operator error is failing to push the *Analyze* or *Shock* buttons when the machine advises you to do so or failing to apply the AED to a patient in cardiac arrest.
- **Application of an AED to a patient who has a pulse.** The computer may be unable to tell the difference between electrical signals from the heart and electrical signals from the arms and chest muscles that are moving. Additionally, most AEDs identify a regular rhythm of faster than 150 or 180 beats/min as VT, which, if pulseless, should be defibrillated. However, a patient in VT with a pulse should be cardioverted (a paramedic skill); defibrillating this patient will most likely result in cardiac arrest. Avoid these errors by using the AED only for pulseless patients.

The main legal risk in using the AED is failing to deliver a shock when one was needed. Of course, the AED is like any other manufactured item. It can fail, although this is rare. Ideally, you will encounter any such failure while performing routine maintenance, not while caring for a patient in cardiac arrest. Check your equipment, including your AED, at the beginning of each shift and exercise the battery as often as the manufacturer recommends. Ask the manufacturer for a checklist of items that should be checked daily, weekly, or less often (**FIGURE 18-14**).

If the AED fails while you are caring for a patient, you must report the problem to the manufacturer and the US Food and Drug Administration. Be sure to follow the appropriate EMS procedures for notifying these organizations.

Medical Direction

Defibrillation of the heart is a medical procedure. Although AEDs have made the process of delivering electricity much simpler, there is still a benefit in

having a physician's involvement. The medical director of your service should help to teach you how to use the AED or, at the least, approve the written protocol that you will follow in caring for patients in cardiac arrest. In most states, AED training in an AEMT course is not permitted without approval by state laws, rules, and local medical direction authority.

There should be a review of each incident in which the AED is used. After returning from the hospital or the scene, discuss with the rest of the team what happened. This discussion will help all members of the team learn from the incident. Review such events by using the written report, any voice-ECG tape recorder, and the device's solid-state memory modules and magnetic tape recordings, if applicable.

There should also be a review of the incident by your service's medical director or quality improvement officer. Quality improvement involves the people using AEDs and the responsible EMS system managers. This review should focus on speed of defibrillation, that is, the time from the call to the time of the shock. Few systems will achieve the ultimate goal: shocking 100% of patients within 1 minute of the call. However, all systems should continuously work on improving patient care. Mandatory continuing education with skill competency review is generally required for EMS providers, with a continuing competency skill review every 3 to 6 months for the AEMT.

Safety

When operating an AED, make sure that no one is injured, including yourself. Be sure no one is touching the patient. Do not defibrillate a patient who is in pooled water. Do not defibrillate someone who is touching metal that others are touching. Finally, carefully remove any medication patches from a patient's chest with your gloved hands, and wipe the area with a dry towel before defibrillation to prevent ignition of the patch.

high-quality CPR and rapid defibrillation, respectively. The importance of high-quality chest compressions during CPR cannot be overstated. This is perhaps the most important intervention you will offer, even more important than defibrillation. Immediate, high-quality CPR markedly increases the patient's chance of survival; a delay leads to poor patient outcomes. Remember to push hard and fast, and ensure the chest completely recoils between each compression; this maximizes blood return to the heart. Finally, do not interrupt compressions unless absolutely necessary.

Preparation for Defibrillation

When dispatch reports an unresponsive patient with CPR in progress, the AED should be one of the first pieces of equipment you obtain from the ambulance. As the operator of the AED, you are responsible for ensuring its safe operation. Remote defibrillation using pads allows you to distance yourself safely from the patient. Do not defibrillate a patient who is in pooled water. Electricity follows the path of least resistance; instead of traveling between the pads and through the patient's heart, it will diffuse into the water. You can defibrillate a wet patient, but first wipe the water from the patient's chest. Prior to defibrillation, ensure that no one is touching any metal that the patient may be in contact with. Carefully remove any NTG or other medication patch from the patient's chest and wipe the area with dry gauze before defibrillation to prevent ignition of the patch. The medication may also be contributing to the cause of the arrest. It is also helpful to shave a hairy patient's chest before pad placement to increase conductivity. Be sure to consult local protocols for issues such as pad placement and preparation of the pad site.

Determine the nature of illness and/or mechanism of injury. If the incident involves trauma, perform spinal immobilization as you begin the primary survey. Is there only one patient? If you are in a tiered system and the patient is in cardiac arrest, call for paramedic assistance.

Indications for not initiating resuscitation techniques include rigor mortis, dependent lividity, and decapitation. Local protocols may also dictate other circumstances, such as advance directives (that is, living wills), do-not-resuscitate orders, and medical orders for life-sustaining treatment (MOLST).

Words of Wisdom

If the AED pads will not stick well due to the amount of hair on the patient's chest, a quick and easy way to remove it is to place the pads firmly in the proper position and then rip them off, pulling the hair out with them. Then place a second set of pads over the area where the hair has been removed. Always make sure you have two sets of pads before using one set for hair removal!

Special Populations

In general, your approach to pediatric patients with a cardiac emergency should be the same as that for an adult. You should attempt to reassure the patient. If possible, administer oxygen. If the patient will not wear a face mask, have the parent hold the oxygen in front of the child's face.

Cardiac arrest in infants and children is usually the result of respiratory failure, not a primary cardiac event. However, the American Heart Association has determined that AEDs are safe to use on infants and children. If the patient is 8 years old or younger, pediatric-size pads and a dose-attenuating system (energy reducer) are preferred. However, if these are unavailable, a regular adult AED can be used. If the child is between 1 month and 1 year of age (an infant), a manual defibrillator is preferred to an AED. If a manual defibrillator is not available, an AED equipped with a pediatric dose attenuator is preferred. If neither is available, an AED without a pediatric dose attenuator may be used. Chapter 35, *Obstetrics and Neonatal Care*, discusses neonatal resuscitation for infants younger than 1 month.

Performing Defibrillation

Prepare with standard precautions en route to the scene. On arrival at the scene, make sure that the scene is safe. Ask any bystanders or first responders who are performing CPR to stop so that you can check for a pulse. Have the compressor continue chest compressions while you apply the AED. Make sure to minimize the time that you are not performing chest compressions; research has shown the best survival rates for patients in whom compressions were interrupted for the least amount of time.⁷ Immediately after each defibrillation, resume high-quality CPR with compressions first. Take the steps shown in **SKILL DRILL 18-2** to use an AED.

Skill Drill 18-2 AED and CPR

Step 1

Assemble equipment, including AED, AED pads, oxygen, and oxygen administration device. Take standard precautions. Ensure scene safety.

Step 2

Assess responsiveness. If the patient is responsive, do not apply the AED. Gather additional information about the arrest event.

Step 3

Check for a carotid pulse while assessing the patient's breathing.

Step 4

If CPR is in progress, assess the effectiveness of chest compressions. If the patient is pulseless and CPR has not been started yet, begin providing chest compressions and rescue breaths at a ratio of 30 compressions to 2 breaths, continuing until an AED arrives and is ready for use. It is important to start chest compressions and use the AED as soon as possible. Compressions provide vital blood flow to the heart and brain, improving the patient's chance of survival.

(continues)

Skill Drill 18-2 AED and CPR (continued)

Step 5

Turn on the AED. Remove clothing from the patient's chest area. With gloves, remove medication paste or patches from the patient's chest, if present, and wipe away any residue.

Step 7

Stop CPR. Verbally and visually clear the patient by stating aloud, "Clear the patient," and ensure that no one is touching the patient. Push the *Analyze* button, if there is one. Wait for the AED to determine whether a shockable rhythm is present. If no shock is advised, perform five cycles (2 minutes) of CPR beginning with chest compressions, then reanalyze the cardiac rhythm. If a shock is advised, restart compressions until the AED is charged, reconfirm that no one is touching the patient, and push the *Shock* button.

Step 6

Apply the AED pads to the chest and attach the pads to the AED: one just to the right of the breastbone (sternum) just below the collarbone (clavicle), the other on the left lower chest area with the top of the pad 2 to 3 inches below the armpit. Do not place the pads on top of breast tissue. If necessary, lift the breast out of the way and place the pad underneath. Ensure that the pads are attached to the patient cables (and that they are attached to the AED in some models). Plug in the pads' connector to the AED.

Step 8

After the shock is delivered, immediately resume CPR beginning with chest compressions. After five cycles (2 minutes) of CPR, reanalyze the cardiac rhythm. Do not interrupt chest compressions for more than 10 seconds. After five cycles (2 minutes) of CPR, reanalyze the cardiac rhythm. Repeat the cycle of 2 minutes of CPR, one shock (if indicated), and 2 minutes of CPR. Transport, and contact medical control as needed.

Safety

When you are “clearing” the patient before an AED shock, ensure that no one is touching the patient and that no one is in contact with any object that is touching the patient, such as the stretcher or a bag-mask device.

If the AED advises no shock and the patient has a pulse, check the patient’s breathing. If the patient is breathing adequately, administer oxygen via a nonrebreathing mask and transport. If the patient is not breathing adequately, provide ventilations with a bag-mask device or pocket mask device attached to 100% oxygen and transport. Ensure that proper airway techniques are used at all times.

Words of Wisdom

Optimally, while performing CPR and using the AED, your patient will regain a pulse. Although you should never use an AED on a patient with a pulse, in this situation, you would leave it in place. However, DO NOT press the **Analyze** button or the **Shock** button as long as the patient maintains a pulse. The AED cannot detect the presence of a pulse, only electrical activity. Defibrillating a patient with a pulse will most likely result in cardiac arrest. In most cases, the AED will not allow you to do this.

Gain IV access, and initiate fluid therapy based on patient status. Give a 250-mL bolus of an isotonic crystalloid solution if hypovolemia is suspected. Determine blood glucose level and give IV dextrose or glucagon if the patient is hypoglycemic.

Provide psychological support for the family and significant others. On arrival at the emergency department, give a full report to the attending staff, including length of time since resuscitation efforts were initiated, how long the patient was “down” before EMS arrival, and any treatment given.

Patient Care After AED Shocks

The care of the patient after the AED delivers its shock depends on your location and the EMS

system; therefore, you should follow your local protocols. After the AED protocol is completed, the patient will have had one of the following occur:

- Pulse is regained
- No pulse, and the AED indicates that no shock is advised
- No pulse, and the AED indicates that a shock is advised

Commonly, in patients who are successfully defibrillated by an AED, a normal heart rhythm will develop. However, if the heart still is not receiving optimal amounts of oxygen, VF will often recur.

Patients who do not regain a pulse on the scene of the cardiac arrest usually do not survive. What you do with these patients, again, depends on your EMS system’s protocols. Whether you should transport the patient or wait for a paramedic unit to arrive should be in the local protocols established by medical control. If paramedics are responding to the scene, the best option usually is to stay where you are and continue the sequence of shocks and CPR. Administering CPR while patients are being moved or transported is usually not effective. The best chance for patient survival occurs when the patient is resuscitated where found, unless the scene is unsafe. See Chapter 15, *BLS Resuscitation*, for a review of BLS for adults, children, and infants.

If paramedics are not responding to the scene and your local protocols agree, you should begin transport when one of the following occurs:

- The patient regains a pulse.
- Six to nine shocks have been delivered (or as directed by local protocol).
- The machine gives three consecutive messages (separated by 2 minutes of CPR) that no shock is advised (or as directed by local protocol).

If you transport a patient while performing CPR, you need a plan for treating the patient in the ambulance. Ideally, you should have two EMS providers in the patient compartment while a third provider drives. You may deliver additional shocks at the scene or en route with the approval of medical control. *Keep in mind that some AEDs cannot analyze rhythm while the vehicle is in motion;* therefore, it is pertinent to be familiar with your equipment and stop if needed. Be sure to memorize the protocol of your EMS service (**FIGURE 18-15**).

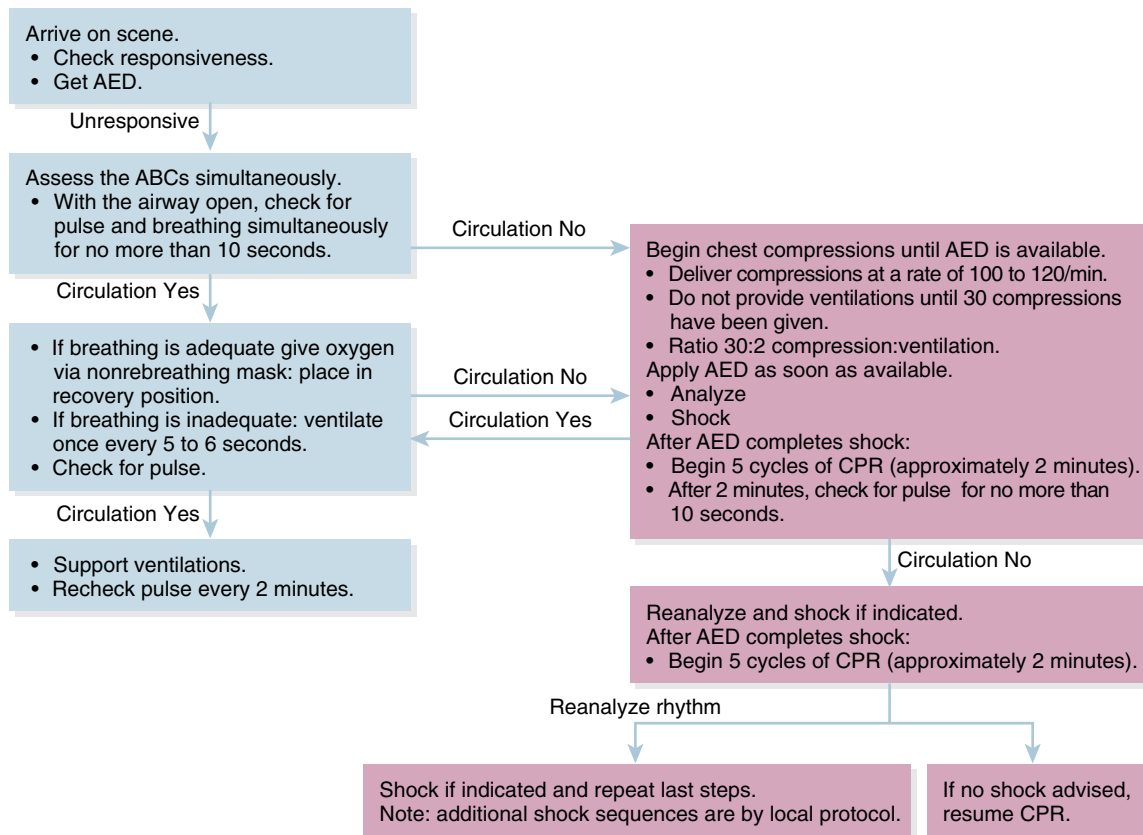

FIGURE 18-15 Automated external defibrillator (AED) algorithm. Follow procedures for return of spontaneous circulation for your region (ie, transport to the appropriate facility, monitor ETCO_2 and vital signs, consider hypothermia, consider obtaining a 12-lead ECG, etc).

© Jones & Bartlett Learning.

Cardiac Arrest During Transport

If you are traveling to the hospital with an unresponsive patient, check the pulse at least every 30 seconds. If a pulse is not present, take the following steps:

1. Stop the vehicle.
2. If the AED is not immediately ready, perform CPR, beginning with chest compressions, until it is available.
3. Analyze the rhythm.
4. Deliver one shock, if indicated, and immediately resume CPR.
5. Continue resuscitation according to your local protocol.

If you are en route with an alert adult patient who is having chest pain and becomes unresponsive, take the following steps:

1. Check for a pulse.
2. Stop the vehicle if no pulse is present.

3. If the AED is not immediately ready, perform CPR, beginning with chest compressions, until it is ready.
4. Analyze the rhythm.
5. Deliver one shock, if indicated, and immediately begin CPR.
6. Begin compressions, and continue resuscitation according to your local protocol, including transporting the patient.

Management of Return of Spontaneous Circulation

Restoration of a pulse after cardiac arrest is called return of spontaneous circulation. If you are able to restore a pulse through the use of CPR and/or an AED, the next steps can be crucial for patient survival. Monitor for spontaneous respirations, provide oxygen via bag-mask device at 10 to 12 breaths/min to maintain ETCO_2 between 35 and 45 mm Hg, and maintain an oxygen saturation between 95% and 99%. Assess blood pressure, and determine if

the patient can follow commands such as “Squeeze my fingers.” Transport patient to the closest appropriate facility depending on local protocol.

Cardiac Monitoring

Some EMS systems will allow AEMTs to place electrodes, attach the leads, and obtain an ECG tracing prior to transport. If your service allows you to perform this skill, the following information will guide you.

For an ECG to be reliable and useful, the electrodes must be placed in consistent positions on each patient. **FIGURE 18-16** shows placement of limb lead electrodes, which are used to obtain a 3-lead ECG. **FIGURE 18-17** shows placement of limb lead electrodes and 12-lead ECG electrodes, both of which are used when obtaining a 12-lead ECG. To maintain consistency in monitoring and obtaining a useful ECG, there are predetermined locations for each electrode. Electrodes used in the prehospital setting are generally adhesive and have a gel center to aid in skin contact. Whichever type is used, certain basic principles should be followed to achieve the best skin contact and minimize **artifact** in the signal. Artifact refers to an ECG tracing that is the result of interference, such as patient movement, rather than the heart's electrical activity. Guiding principles are as follows:

- To maintain the correct lead placement, it may occasionally be necessary to shave body hair

from the electrode site. A hairy chest may initially appear to have good skin contact, but the electrode will rise off the skin and stick to the hair. If you must shave the site, be very careful to avoid nicking the skin. If one is available, it is best to use an electric razor to remove hair, because single-blade manual razors irritate the skin and can easily cut a patient.

- To remove oils and dead tissues from the surface of the skin, rub the electrode site briskly with an alcohol swab before application. Wait for the alcohol to dry before applying electrodes or dry it with a quick wipe of a 4 × 4-inch (10 × 10-cm) gauze pad. This step may have to be repeated if the patient is sweaty, as many cardiac patients are.
- Attach the electrodes to the ECG cables before placement. Confirm that the appropriate electrode (now attached to the cable) is placed at the correct location on the patient's chest or limbs. (Each cable is marked and color coded as to the correct location for placement.)
- When all electrodes are in place, switch on the monitor and print a sample rhythm strip.

FIGURE 18-16 Limb electrode placement for acquisition of a 3-lead electrocardiogram and cardiac monitoring.

© Jones & Bartlett Learning.

Lead	Location	View
V ₁	4th intercostal space, right sternal border	Ventricular septum
V ₂	4th intercostal space, left sternal border	Ventricular septum
V ₃	Between V ₂ and V ₄	Anterior wall of left ventricle
V ₄	5th intercostal space, midclavicular line	Anterior wall of left ventricle
V ₅	Lateral to V ₄ at the anterior axillary line	Lateral wall of left ventricle
V ₆	Lateral to V ₅ at the midaxillary line	Lateral wall of left ventricle

FIGURE 18-17 12-lead ECG electrode placement.

© Jones & Bartlett Learning.

If the strip shows any interference (artifact), verify that the electrodes are firmly applied to the skin and the monitor cable is plugged in correctly.

Artifact on the monitor can be tricky. Patient movement, including deep breathing or muscle tremor, may cause a wavy baseline or small

up-and-down squiggles on the baseline. These will prevent the ECG from being usable. Make sure that the patient is supine if possible, or in the semi-Fowler position if they are having difficulty breathing. Also make sure that the patient's arms are relaxed by their sides and the feet are uncrossed.

SKILL DRILL 18-3 shows the steps for performing cardiac monitoring.

Street Smarts

Reviewing the ECG

Identification of cardiac rhythms is a paramedic-level skill, but as an AEMT you will likely become familiar with some of the common rhythms. When interpreting an ECG tracing, begin by ensuring you have a high-quality printout. You should be able to see the QRS complexes (the largest, usually narrow, deflections on the ECG) clearly without interference from artifact. Each QRS complex represents one contraction of the ventricles, so the closer together they are, the faster the heartbeat. The horizontal distance between each wave on the ECG represents time passing. Each small (1-mm) box on the printout represents 0.04 second, and each of the larger (5-mm) boxes represent 0.20 second. The QRS complex should be less than 3 mm wide from where it starts to leave the baseline to where it returns. QRS complexes that are wider than 3 mm are usually signs of dangerous rhythms.

If two QRS complexes are less than 15 mm apart (three large boxes), the heart rate is over 100 and the rhythm is a tachycardia. If the QRS complexes are more than 25 mm apart (five large boxes), the rate is less than 60 beats per minute and the rhythm is a bradycardia. Rhythms such as tachycardia and bradycardia may cause a patient to have altered mental status or hypotension.

You may also see a small rounded wave before the QRS called a P wave, which represents the contraction of the atria. After each QRS complex, you should see a T wave that represents the repolarization (or recharging) of the ventricles. The horizontal line between all waves is called the baseline and segments of the baseline are often identified by the waves they connect. For example, the ST segment connects the end of the QRS complex and the beginning of the T wave. Elevation of this ST segment above the baseline in a 12-lead ECG can be an indication of a myocardial infarction in progress.

Skill Drill 18-3 Performing Cardiac Monitoring

Step 1

Take standard precautions.

Step 2

Explain the procedure to the patient. Prepare the skin for electrode placement.

Skill Drill 18-3 Performing Cardiac Monitoring (continued)

Step 3

Attach the electrodes to the leads before placing them on the patient.

Step 5

If you plan to obtain a 12-lead ECG tracing, place the chest leads on the chest as follows:

- The V_1 electrode is placed on the right side of the sternum between the fourth and fifth ribs.
- The V_2 electrode is placed on the left side of the sternum directly across from V_1 .
- The V_4 is placed next, between the fifth and sixth ribs in a straight line down from the middle of the clavicle.
- The V_3 is then placed halfway between V_2 and V_4 .
- The V_6 is placed next and is located horizontally even with V_4 in a straight line down from the middle of the armpit.
- Finally, V_5 is placed halfway between V_4 and V_6 .

Step 4

Position the limb electrodes on the patient, on the torso if performing continuous monitoring, on the limbs if you will be acquiring a 12-lead ECG. The RA (right arm) electrode goes on the right arm distal to the shoulder or on the wrist (avoid placing it directly over a bone). The LA (left arm) electrode goes on the left arm at the same location as you placed the RA electrode on the right arm. The LL (left leg) electrode is placed on the left leg on the thigh or ankle, although if you do not plan to obtain a 12-lead ECG tracing, this electrode is often placed on the lower left side of the abdomen (slightly lower than an AED pad would be placed). Place the RL (right leg) electrode at the same location on the right side of the body as the LL electrode on the left.

Step 6

Turn on the monitor.

(continues)

Skill Drill 18-3 Performing Cardiac Monitoring (continued)

Step 7

Record tracings. As soon as a rhythm is visible on the screen, press the print button on the monitor and print a strip while counting slowly to six or seven. Then press the print button again to stop the printout. If the time is not printed correctly on the strip, write it on the edge of the strip. If you are obtaining a 12-lead ECG tracing, ask the patient to hold their breath or to take very shallow breaths. Press the 12-lead button and wait for the machine to acquire, analyze, and print or transmit the 12-lead ECG tracing. Gently tear off the tracing when the printer automatically stops.

© Jones & Bartlett Learning.

Step 8

Label each strip.

YOU are the Provider SUMMARY

1. How does the heart become oxygenated?

The heart, like any other muscle, requires oxygen and nutrients. These substances are supplied via the coronary arteries, which arise from the aorta shortly after it leaves the left ventricle. The coronary circulation emanates from the left and right coronary arteries.

The right coronary artery generally divides into nine branches. These branches supply blood to the walls of the right atrium and ventricle, a portion of the inferior part of the left ventricle, and portions of the conduction system.

The left main coronary artery is the widest and shortest of the myocardial blood vessels. It rapidly divides into two branches: the left anterior descending

artery and the circumflex coronary artery. These arteries subdivide further, supplying blood to most of the left ventricle, the interventricular septum, and, at times, the AV node.

2. What is the most common cause of chest pain?

Chest pain or discomfort that is related to the heart usually stems from a condition called ischemia, which is decreased blood flow, in this case, to the heart. Because of a partial or complete blockage of blood flow through the coronary arteries, heart tissue fails to get enough oxygen and nutrients. The tissue soon begins to starve and eventually dies if blood flow is not restored.

YOU are the Provider SUMMARY *continued***3. In which medication class is aspirin, and what are the indications and contraindications for administration?**

Aspirin, acetylsalicylic acid, is classified as a platelet inhibitor and a nonsteroidal anti-inflammatory agent. Indications for administration of aspirin include new-onset chest pain, suggesting AMI. Contraindications for administration include hypersensitivity to aspirin; also, aspirin is relatively contraindicated in patients with active ulcer disease or asthma. Adverse reactions you may encounter include heartburn, gastrointestinal bleeding, nausea, and vomiting.

4. What is the mechanism of action of nitroglycerin, and what are the indications and contraindications?

NTG is a vasodilator. It relaxes smooth muscles in the body, including those in the vasculature. This causes dilation of the arterioles and veins in the periphery, which reduces preload and afterload. In doing this, NTG reduces the workload of the heart which also reduces myocardial oxygen demand. NTG is indicated in patients with acute angina pectoris, ischemic chest pain, hypertension, heart failure, and pulmonary edema. NTG should not be given to patients experiencing hypotension, hypovolemia, intracranial bleeding, or head injuries. NTG should also not be given to patients who have taken Viagra, Revatio, Levitra, Cialis, or similar agents within the past 24 to 72 hours.

5. What are the various routes available to administer nitroglycerin?

NTG comes in several forms and may be administered several ways. Forms include a small white pill given sublingually, a spray administered sublingually, or a topical patch or paste applied to the skin. NTG can also be administered as a liquid continuous infusion by paramedics or in the hospital. Regardless of the form or route that it is administered, the effects are the same.

6. Does this patient require IV access?

It might be beneficial to establish IV access (a saline lock) in this patient. However, establishing IV access should not take precedence over transport. Whereas

this patient is not currently hypovolemic, she may require the administration of IV fluid en route to the hospital, should hypovolemia develop as a result of the administration of NTG or deterioration of the cardiovascular system (the pump). Patients who are experiencing a possible AMI are also potential candidates for cardiac arrest. It is much easier to obtain IV access while the patient has a pulse.

7. Should paramedic backup be requested for this patient?

Again, if you suspect that this patient is experiencing an AMI, paramedic backup should be requested. This patient has the potential to go into cardiac arrest from potential dysrhythmias, as well as potentially benefiting from narcotic administration if the chest pain persists. Having paramedics treat this patient may increase her chance of survival. Do not delay transport while waiting; instead, have the paramedic unit rendezvous at a point on the way to the hospital.

8. What is the most common error with AED operation?

The most common error with AED operation is failure to have a charged and operable battery. To avoid this problem, many defibrillator companies have built smarter machines that will warn the operator that the battery is unlikely to work. However, some of the older models do not have this feature. You should check the AED daily, and exercise the battery as often as the manufacturer recommends.

9. What are the six links in the chain of survival?

The six links in the chain of survival are immediate recognition of warning signs and activation of EMS, immediate CPR with emphasis on high-quality chest compressions, rapid defibrillation, effective basic and advanced EMS care, ALS postarrest care, and recovery.

If any one of the links in the chain is absent or delayed, the patient's chances for survival diminish. For example, few patients benefit from defibrillation when more than 10 minutes elapse before administration of the first shock or if CPR is not performed in the first 2 to 3 minutes. If all links in the chain are strong, the patient has the best possible chance of survival.

Narrative

EMS dispatched to above location for a 56 y/o female complaining of chest pain. On arrival, patient found in fetal position on sofa, rocking back and forth, moaning in pain. Patient presents AOx4, ABCs intact, states she has an extensive cardiac history, with last MI in 2018. Placed patient on 15 L/min, primary survey reveals no signs of trauma. States pain woke her up from a nap, described as an "elephant sitting on her chest," which radiates to left arm. Pain 9/10. Vitals obtained as above. In accordance with protocols, patient administered 324 mg aspirin orally, and 0.4 mg of NTG via sublingual route, which brought pain to 2/10. Placed patient on stretcher and secured, loaded into ambulance. Vital signs reassessed, 22-gauge saline lock established to right wrist. Contacted Central Medical dispatch for paramedic intercept, advised no units available. Transport emergent to First Care ED due to Unity not having cardiac services available. At 1555, patient reports increasing chest pain, per protocols, 0.4 mg NTG given via SL route. Approximately 90 seconds after administration, patient becomes pulseless and apneic. Ambulance stopped, AED applied, and patient analyzed. Patient defibrillated once per AED. One-person CPR initiated and diverted to Unity Hospital. On arrival, care and report given to ED staff without further incident.

End of report

Prep Kit

Ready for Review

- Cardiovascular diseases are the number one cause of death in men and women. Although older people are at a higher risk, such a sweeping generalization overlooks a large number of younger people. For these reasons, early recognition and early treatment are the keys to survival.
- The heart is divided down the middle into two sides, right and left, each with an upper chamber called the atrium and a lower chamber called the ventricle.
- The largest of the four heart valves that keep blood moving through the circulatory system in the proper direction is the aortic valve, which lies between the left ventricle and the aorta, the body's main artery.
- The heart's electrical conduction system controls heart rate and helps to keep the atria and ventricles working together. The mechanical pumping action of the heart can occur only in response to an electrical stimulus.
- Cardiac muscle cells have a special characteristic called automaticity. Automaticity allows a cardiac muscle cell to contract spontaneously without a stimulus from a nerve source. Impulses from the sinoatrial node cause the other myocardial cells to contract.
- Regulation of heart function is provided by the brain via the autonomic nervous system, the hormones of the endocrine system, and the heart tissue. Baroreceptors and chemoreceptors sense abnormalities in pressure and chemical composition.
- The two phases of the cardiac cycle are systole, the pumping phase, and diastole, the resting phase.
- During periods of exertion or stress, the myocardium requires more oxygen. This is supplied by dilation of the coronary arteries, which increases blood flow.
- Chest pain or discomfort that is related to the heart usually stems from ischemia (decreased blood flow) to the heart. The tissue soon begins to starve and, if blood flow is not restored, eventually dies.
- Diminished blood flow to the myocardium is usually caused by atherosclerosis, a disorder in which cholesterol and other fatty substances build up and form plaque inside the walls of blood vessels.
- Occasionally, brittle plaque will crack, causing a blood clot to form. A blood clot may break loose and begin floating in the blood, becoming what is known as a thromboembolism. A thromboembolism floats through blood vessels until it reaches an area too narrow for it to pass, causing it to stop and block the blood flow at that point.
- Heart tissue downstream suffers from a lack of oxygen and, within 30 minutes, will begin to die. This is called an AMI, or heart attack.
- Chest pain may be caused by a brief period when heart tissues do not get enough oxygen. The discomfort associated with this is called angina. Angina pain is similar to the pain of an AMI, but responds to NTG administration. However, angina can be a sign that an AMI will occur in the future.
- Myocardial tissues that are ischemic but are not yet dying can cause pain called angina. The pain of AMI is different from that of angina in that it can come at any time, not just with exertion; it lasts up to several hours, rather than just a few moments; and it is not relieved by rest or NTG.
- In addition to chest pain or pressure, signs of AMI include sudden onset of weakness, nausea, and sweating; sudden dysrhythmia; pulmonary edema; and even sudden death.
- Heart attacks can have three serious consequences:
 - The first is sudden death, usually the result of cardiac arrest caused by dysrhythmias (abnormal heart rhythms). These include tachycardia, bradycardia, VT, and, most commonly, VF.

- The second consequence is cardiogenic shock. Symptoms include restlessness; anxiety; pale, clammy skin; pulse rate higher than normal; and blood pressure lower than normal. Patients with these symptoms should receive oxygen, assisted ventilation as needed, and immediate transport.
- The third consequence of AMI is heart failure, in which the damaged myocardium can no longer contract effectively enough to pump blood through the system. The lungs become congested with fluid, breathing becomes difficult, the heart rate increases, and the left ventricle enlarges.
- Signs of heart failure include swollen ankles from pedal edema, high blood pressure, rapid heart rate and respirations, rales, and sometimes the pink sputum and dyspnea of pulmonary edema.
- Treat a patient with heart failure as you would a patient with chest pain. Monitor the patient's vital signs. Give the patient oxygen via a non-rebreathing mask. Allow the patient to remain sitting up.
- In treating patients with chest pain, obtain a SAMPLE history, following the OPQRST-I mnemonic to assess the pain; measure and record vital signs; ensure that the patient is in a comfortable position, usually semireclining or half sitting up; administer prescribed NTG, aspirin, and oxygen; and transport the patient, reporting to medical control as you do.
- Follow local protocols to treat a patient in cardiac arrest. Ensure a patent airway and obtain an advanced airway as soon as possible. Establish IV access.
- Termination of efforts should be based on local protocol and direct communication with on-line medical control.
- The AED requires the operator to apply the pads, power on the unit, follow the AED prompts, and press the *Shock* button if indicated. The computer inside the AED recognizes rhythms that require shock.
- The most common errors in using certain AEDs are operator failure (such as failure to keep a charged battery), failure to use the AED correctly, and applying the AED to a patient with a pulse.
- Do not touch the patient while the AED is analyzing the heart rhythm or delivering shocks.
- Approach to pediatric patients with a cardiac emergency should be the same as that for an adult. If the patient is 8 years old or younger, pediatric-size pads and a dose-attenuating system (energy reducer) are preferred. If these are not available, an adult AED can be used. For a child between age 1 month and 1 year (an infant), a manual defibrillator is preferred to an AED.
- Effective CPR and rapid defibrillation with an AED are critical interventions to the survival of a patient in cardiac arrest. If the patient is in cardiac arrest, start CPR, beginning with high-quality chest compressions, and apply the AED as soon as it is available.
- If paramedics are responding to the scene, stay where you are and continue CPR and defibrillation as needed. Do not wait for the paramedics to arrive to begin defibrillation. If paramedics are not responding, begin transport if the patient regains a pulse, if you have delivered six to nine shocks, or if the AED gives three consecutive messages (separated by 2 minutes of CPR) that no shock is advised. Follow your local protocols regarding when it is appropriate to transport the patient.
- If an unresponsive patient has a pulse but loses it during transport, you must stop the vehicle, reanalyze the rhythm, and defibrillate again or begin CPR, as appropriate.
- The chain of survival, which is the sequence of events that must happen for a patient in cardiac arrest to have the best chance of survival, includes recognition of early warning signs and immediate activation of EMS, immediate CPR with emphasis on high-quality chest compressions, rapid defibrillation, basic and

advanced EMS care, ALS and postarrest care, and recovery.

- Your role as the advanced emergency medical technician may include obtaining an ECG.

Vital Vocabulary

acute coronary syndrome (ACS) A term used to describe a group of symptoms caused by myocardial ischemia; includes angina and myocardial infarction.

acute myocardial infarction (AMI) Heart attack; death of heart muscle following obstruction of blood flow to it. Acute in this context means new or happening right now.

afterload The pressure in the aorta against which the left ventricle must pump blood; increasing this pressure can decrease cardiac output.

angina pectoris Transient (short-lived) chest discomfort caused by partial or temporary blockage of blood flow to the heart muscle.

aorta The main artery that receives blood from the left ventricle and delivers it to all the other arteries that carry blood to the tissues of the body.

aortic aneurysm A weakness in the wall of the aorta that makes it susceptible to rupture.

aortic valve The one-way, semilunar valve that lies between the left ventricle and the aorta; keeps blood from flowing back into the left ventricle after the left ventricle ejects its blood into the aorta and is one of four heart valves.

arteries Vessels of the circulatory system that carry oxygenated blood away from the heart.

arterioles The smallest branches of arteries leading to the vast network of capillaries.

arteriosclerosis The thickening of the arterial walls that results in a loss of elasticity and concomitant reduction in blood flow.

artifact A tracing on an electrocardiogram that is the result of interference, such as patient movement, rather than the heart's electrical activity.

asystole Complete absence of heart electrical activity.

For example, you may place electrodes, attach leads, and obtain the tracing. Whether for 3-lead or 12-lead monitoring, it is important for electrode placement to be consistent.

atherosclerosis A disorder in which cholesterol and possibly calcium build up inside the walls of blood vessels, forming plaque, which eventually leads to partial or complete blockage of blood flow; a plaque can become a site where blood clots can form, detach, and travel elsewhere in the circulatory system (embolize); the most common form of arteriosclerosis.

atrioventricular (AV) node The site located in the right atrium adjacent to the septum that is responsible for transiently slowing electrical conduction.

atrioventricular valves The two valves through which blood flows from the atria to the ventricles.

atrium One of two (right and left) upper chambers of the heart.

automaticity The ability of cardiac cells to generate an impulse to contract even when there is no external nervous stimulus.

autonomic nervous system The part of the nervous system that regulates functions that are not controlled consciously, but rather involuntarily, such as heart rate, blood pressure, digestion, and sweating.

baroreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in pressure in the heart or main arteries to help maintain homeostasis.

bradycardia A slow heart rate; less than 60 beats/min in adults; less than 80 beats/min in children; and less than 100 beats/min in infants.

capillaries Microscopic, thin-walled blood vessels between the arterioles and venules through which oxygen, carbon dioxide, nutrients, and waste products are exchanged between body tissues and the blood.

cardiac arrest A state in which the heart fails to generate an effective and detectable blood flow; pulses are not palpable in cardiac arrest, even if muscular and electrical activity continues in the heart.

cardiac cycle The repetitive pumping process that begins with the onset of cardiac muscle contraction and ends just before the beginning of the next contraction.

cardiac output The amount of blood pumped by the heart per minute; calculated by multiplying the stroke volume by the pulse rate per minute.

cardiogenic shock Shock caused by inadequate function of the heart, or pump failure; caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery; can be a severe complication of a large acute myocardial infarction, as well as other conditions.

chemoreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in chemical composition of the blood to help maintain homeostasis.

chordae tendineae Thin bands of fibrous tissue that attach to the valves in the heart and prevent them from inverting, preventing regurgitation of blood through the valves from the ventricles to the atria.

chronotropic state Related to the control of the heart's rate of contraction.

circumflex coronary artery One of the two branches of the left main coronary artery.

conduction system A group of complex electrical tissues within the heart that initiate and transmit stimuli that result in contractions of myocardial tissue.

conductivity The ability of the cardiac cells to conduct electrical impulses.

contractility The strength of heart muscle contraction.

coronary arteries Arteries that arise from the aorta shortly after it leaves the left ventricle and supply the heart with oxygen and nutrients.

coronary artery disease The condition that results when atherosclerosis or arteriosclerosis is present in the arterial walls.

coronary sinus The end of the great cardiac vein that collects blood returning from the walls of the heart.

defibrillate To shock a fibrillating (chaotically beating) heart with specialized electrical current in an attempt to restore a normal rhythmic beat.

dependent edema Swelling in the part of the body closest to the ground, caused by collection of fluid in the tissues; a possible sign of heart failure.

diastole The relaxation phase of the heart, when the ventricles are filling with blood.

dissecting aneurysm A condition in which the inner layers of an artery, such as the aorta, become separated, allowing blood (at high pressures) to flow between the layers.

dromotropic state Related to the control of the heart's conduction rate.

dysrhythmia An irregular or abnormal heart rhythm.

ejection fraction The portion of the blood ejected from the ventricle during systole.

endocardium The thin membrane lining the inside of the heart.

epicardium The layer of the serous pericardium that lies closely against the heart; also called the visceral pericardium.

excitability A property of cardiac cells that provides the cells with the ability to respond to electrical impulses.

fibrinolytic therapy The use of medications that act to dissolve blood clots.

heart A hollow muscular organ that pumps blood throughout the body.

heart failure A disorder in which the heart loses part of its ability to effectively pump blood, usually as a result of damage to the heart muscle and usually resulting in a backup of fluid into the lungs.

hemoglobin An iron-containing protein within red blood cells that has the ability to combine with oxygen; carries 97% of oxygen.

hypertensive emergency An emergency situation created by excessively high blood pressure, which can lead to serious complications such as stroke or aneurysm.

inferior vena cava One of the two largest veins in the body; carries blood from the lower extremities and the pelvic and the abdominal organs to the heart.

inotropic state Related to the strength of the heart's contraction.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially reversible because permanent injury has not yet occurred.

left anterior descending (LAD) artery One of the two branches of the left main coronary artery, which is the largest and shortest of the myocardial blood vessels; this and the circumflex coronary artery supply blood to the left ventricle and other areas.

lumen The inside diameter of an artery or other hollow structure.

mitral valve The valve in the heart that separates the left atrium from the left ventricle.

myocardium The heart muscle.

occlusion Blockage, usually of a tubular structure such as a blood vessel.

orthopnea Severe dyspnea experienced when lying down that is relieved by a change in position, such as sitting up or standing.

papillary muscles Specialized muscles that attach the ventricles to the cusps of the valves by muscular strands called chordae tendineae cordis.

pedal edema Swelling of the feet and ankles caused by collection of fluid in the tissues; a possible sign of heart failure.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

pericardial fluid A serous fluid that fills the space between the visceral pericardium and the parietal pericardium and helps to reduce friction.

pericardial sac A thick, fibrous membrane that surrounds the heart; also called the pericardium.

pericardium A thick, fibrous membrane that surrounds the heart; also called the pericardial sac.

plasma A sticky, yellow fluid made mostly of water, but also electrolytes, clotting factors, and glucose, that is a component of blood that carries the blood cells, formed elements, and nutrients and transports cellular waste material to the organs of excretion.

platelets Tiny, disk-shaped elements that are much smaller than the cells; they are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

preload The precontraction pressure in the heart, which increases as the volume of blood builds up when returned to the heart (venous return); directly affects afterload.

pulmonary circulation The flow of blood from the right ventricle through the pulmonary arteries and all of their branches and capillaries in the lungs and back to the left atrium through the venules and pulmonary veins; also called the lesser circulation.

pulmonic valve The semilunar valve that regulates blood flow between the right ventricle and the pulmonary artery.

red blood cells (RBCs) The formed elements in the blood that contain hemoglobin and are responsible for carrying oxygen to the tissues; also called erythrocytes.

semilunar valves The two valves, the aortic and pulmonic valves, that divide the heart from the aorta and pulmonary arteries.

sinoatrial (SA) node The normal site of the origin of electrical impulses; located high in the right atrium, it is the heart's natural pacemaker.

Starling law A principle that states that if a muscle is stretched slightly before stimulation

to contract, the muscle will contract harder; describes how increased venous return to the heart stretches the ventricles and allows for increased cardiac contractility.

stroke volume The volume of blood pumped forward from the left ventricle into the aorta with each ventricular contraction.

superior vena cava The principal vein draining blood from the upper portion of the body.

systemic circulation The circulatory system in the body that is responsible for blood flow in all areas of the body, except for areas covered by the pulmonary circulation (blood flow from the right side of the heart to the lungs and back to the left side of the heart).

systole The contraction, or period of contraction, of the heart, especially that of the ventricles.

tachycardia A rapid heart rate of more than 100 beats per minute in an adult.

thromboembolism A blood clot that has formed within a blood vessel and is floating within the bloodstream.

tricuspid valve The heart valve that separates the right atrium from the right ventricle.

veins The blood vessels that transport unoxygenated blood back to the heart.

ventricle In the context of the circulatory system, one of two lower chambers of the heart; in the context of the neurologic system, hollow storage areas in the brain.

ventricular fibrillation (VF) Disorganized, ineffective twitching of the ventricles, resulting in no blood flow and a state of cardiac arrest.

ventricular tachycardia (VT) Rapid heart rhythm in which the electrical impulse begins in the ventricle (instead of the atrium), which may result in inadequate blood flow and eventually deteriorate into cardiac arrest.

venules Very small, thin-walled vessels that connect capillaries to larger veins.

white blood cells (WBCs) Blood cells that have a role in the body's immune defense mechanisms; they provide immunity, fight infection, and remove dead cells; also called leukocytes.

Chapter 19

Neurologic Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Neurology

Anatomy, presentations, and management of

- Decreased level of responsiveness (pp 1001, 1003–1005)

Anatomy, physiology, pathophysiology, assessment, and management of

- Seizure (pp 1003–1007, 1023–1025)
- Stroke/transient ischemic attack (pp 997–1003, 1015–1023)
- Status epilepticus (pp 1005, 1011, 1020)
- Headache (pp 1009–1010, 1026)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the brain and spinal cord. (pp 993–994)
2. List the various ways blood flow to the brain may be interrupted and cause a stroke. (pp 997–998)
3. Discuss the causes of ischemic strokes, hemorrhagic strokes, and transient ischemic attacks (TIAs), and their similarities and differences. (pp 998–1001)
4. Discuss the different types of headaches, the possible causes of each, and how to distinguish a harmless headache from a potentially life-threatening condition. (pp 1009–1011)
5. Describe the dangers associated with increased intracranial pressure (ICP) and the processes that occur in the brain with increased ICP. (p 1000)
6. List the general signs and symptoms of stroke, and identify those symptoms that manifest if the left hemisphere of the brain is affected, if the right hemisphere of the brain is affected, and if there is bleeding in the brain. (pp 1001–1002)
7. Discuss three conditions with symptoms that mimic stroke and the assessment techniques the advanced emergency medical technician (AEMT) may use to identify them. (pp 1002–1003)
8. Define a generalized seizure, focal seizure, and status epilepticus, including their effects on a patient and how they differ from each other. (pp 1003, 1005)
9. Describe the different phases of a seizure. (pp 1003–1005)
10. List the different types of seizures and their possible causes. (pp 1005–1006)
11. Explain why it is important for the AEMT to recognize when a seizure is occurring or whether one has already occurred in a patient and to identify other problems that may be associated with the seizure. (pp 1006–1007)
12. Describe the postictal state and the specific patient care interventions that may be necessary to assist the patient. (p 1007)

13. Define altered mental status, its various possible causes, and the patient assessment considerations that apply to each. (pp 1007–1009)
14. Discuss scene safety considerations when responding to a patient with a neurologic emergency. (pp 1010–1011)
15. Describe the steps involved in performing a primary survey of a patient who is experiencing a neurologic emergency and the necessary interventions that may be required to address all life threats. (pp 1011–1013)
16. Discuss the special considerations required for pediatric patients who exhibit altered mental status. (p 1014)
17. Discuss special considerations for geriatric patients who are experiencing a neurologic emergency. (p 1014)
18. Describe the process of history taking for a patient who is experiencing a neurologic emergency, and explain how this process varies depending on the nature of the patient's illness. (pp 1014–1015)
19. Discuss how to use a stroke assessment tool to identify a stroke patient rapidly, giving examples of two commonly used tools. (pp 1015–1016)
20. List the key information an AEMT must obtain and document for a stroke patient during assessment and reassessment. (pp 1018–1020)
21. Explain why a patient who is suspected of experiencing a stroke is placed on stroke alert and requires treatment within the first 3 to 6 hours after the stroke begins. (p 1020)
22. Describe the patient management, treatment, and transport of patients who are experiencing headaches, stroke, seizure, or altered mental status. (pp 1021–1026)

SKILLS OBJECTIVES

1. Demonstrate how to use a stroke assessment tool such as the Cincinnati Prehospital Stroke Scale to test a patient for aphasia, facial weakness, and motor weakness. (pp 1015–1016)

Introduction

The National Center for Health Statistics lists two of the top 10 causes of death in the United States in 2017 as neurologic in nature.¹ **Stroke**, a serious medical condition in which blood supply to areas of the brain is interrupted, is the fifth leading cause of death in the United States, after heart disease, cancer, accidents, and chronic lower respiratory diseases.¹ The sixth leading cause of death is Alzheimer disease.¹ Given the relative frequency of these conditions, it is clear that advanced emergency medical technicians (AEMTs) will encounter many neurologic emergencies.

Over the past 20 years, there has been a revolution in the treatment of stroke.² Treatments are based on the type of stroke—ischemic or hemorrhagic—and range from more traditional medications for breaking up clots to new, innovative surgical procedures such as mechanical clot removal in cerebral ischemia (MERCi) and arteriovenous malformation repair.³ Emergency physicians, neurologists, and neurosurgeons can help some patients with acute stroke avoid the most

devastating consequences of this disease, providing that signs and symptoms are recognized early on and that they receive prompt care.

Seizures and altered mental status also occur when there is a disorder in the brain. Seizures may occur as a result of a recent or an old head injury, a brain tumor, a metabolic problem, a genetic predisposition, scar tissue from a stroke, or an unknown cause. Your ability to recognize when a seizure has occurred or is occurring is critical for the patient because this information helps direct the most appropriate treatment.

Altered mental status is a common presentation in patients with a wide variety of medical problems. You should not make assumptions about the cause of altered mental status, which can range from alcohol intoxication, to head injury, to diabetic emergency, to stroke. Treatment varies widely, depending on the underlying cause. The care for patients with altered mental status presents a particular challenge because the patients may be difficult to handle and frustrating to treat at times. Your professionalism is paramount in these situations.

Neurologic patients can be extremely vulnerable or even helpless. Many of the reflexes that protect an awake person may not function when the nervous system is depressed. The eyelids do not blink away dust and irritants. The pharynx does not produce the gag reflex and the cough reflex is not stimulated in reaction to secretions draining down or foreign matter in the airway. The body does not seek a more comfortable position in response to compression of a limb in an awkward position. The tongue becomes flaccid. The airway is at risk.

In this chapter, you will learn how to approach and assess a patient with a brain disorder and the indications for prompt transport to an appropriate medical facility.

Anatomy and Physiology Review

The nervous system is the most complex organ system within the human body. It consists of two major structures, the brain and spinal cord, plus thousands of nerves allowing communication among all parts of the body. This system is responsible for fundamental functions such as controlling breathing, heart rate, blood pressure, and temperature, and higher-level activities such as memory, understanding, communication, and thought.

The basic organization of the nervous system is shown in **FIGURE 19-1**. Recall that the major structures of the nervous system are divided into two

FIGURE 19-1 Basic organization of the nervous system.

YOU are the Provider

Part 1

At 0354 hours, just as you are leaving the emergency department from your last call, dispatch advises you to respond to a local homeless shelter for a severely intoxicated person with slurred speech. You and your partner give each other a knowing look and respond to the scene. On your arrival, you encounter a 62-year-old man who is a patient you frequently see because of intoxication. He is sitting on the ground, leaning against the wall for support. As you begin your assessment, you notice slurred speech, which is common for him when he is intoxicated. However, you also notice some right-side facial droop and possible left-side weakness.

1. What mnemonic is useful for assessing adult patients with altered mental status?
2. What are the two types of abnormal posturing, and what do they indicate?

FIGURE 19-2 The brain is well protected within the skull. The brain's major parts are the cerebrum, the cerebellum, and the brainstem.

© Jones Bartlett Learning.

main categories: the central nervous system (CNS), which is responsible for thought, perception, feeling, and autonomic body functions; and the peripheral nervous system (PNS), which transmits commands from the brain to the body and receives feedback from the body.

The brain controls breathing, speech, and all other body functions. Different parts of the brain perform different functions. For example, some parts of the brain receive input from the senses, including sight, hearing, taste, smell, and touch; some control the muscles and movement, whereas others control the formation of speech.

The brain is divided into three major parts: the brainstem; the cerebellum; and the largest part, the cerebrum (**FIGURE 19-2**). The brainstem controls the most basic functions of the body, such as breathing, blood pressure, swallowing, and pupil constriction. Located just behind the brainstem, the cerebellum controls muscle and body coordination. It is responsible for coordinating complex tasks that involve voluntary movement of muscles, such as walking, writing, and playing the piano.

The cerebrum, located above the cerebellum, is divided down the middle into the right and left cerebral hemispheres. Each hemisphere controls activities on the opposite side of the body. The front part of the cerebrum controls emotion and thought, and the middle part controls touch and movement. The back part of the cerebrum

FIGURE 19-3 The spinal cord is the continuation of the brainstem. It exits the skull at the foramen magnum and extends down to the level of the second lumbar vertebra.

© Jones & Bartlett Learning.

processes sight. In most people, speech is controlled on the left side of the brain near the middle of the cerebrum.

Messages sent to and from the brain travel through nerves. Twelve cranial nerves run directly from the brain to various parts of the head, such as the eyes, ears, nose, and face. The rest of the nerves join in the spinal cord and exit the brain through a large opening in the base of the skull called the foramen magnum (**FIGURE 19-3**). At each vertebra in the neck and back, two nerves, called spinal nerves, branch out from the spinal cord and carry signals to and from the body; the areas of skin sensation corresponding to specific spinal nerves are called dermatomes (**FIGURE 19-4**).

Neurons and Impulse Transmission

A neuron is a nerve cell and is the fundamental element of the nervous system. Neurons are composed of three basic parts: the cell body, the axon, and dendrites. The cell body contains the nucleus. The **axon** is a projection from the cell body that extends

FIGURE 19-4 Dermatome map showing the association of the spinal nerves and the skin sensation throughout areas of the body.

© Jones & Bartlett Learning.

toward another cell carrying signals away from the neuron. The axon may or may not be wrapped in a sheath of **myelin**, an insulating substance that allows the cell to transmit its signal efficiently and consistently, without “shorting out” or losing electricity to surrounding fluids and tissues. Myelin also increases the speed of conduction. Most of the neurons within the body have a myelin sheath.

Synapses

Interaction between two neurons occurs at a junction known as a **synapse**. Nerve cells do not actually come in direct contact with each other. There is a slight gap between each cell. This allows for a far greater level of fine control than if each cell were in direct contact with the next. The synapse, which is present wherever a nerve cell terminates, “connects” one nerve cell to the next cell. This communication occurs through the release of chemicals called neurotransmitters from the first cell. These chemicals cross the synapse and interact with the second cell, triggering a message.

Neurotransmitters

Most neurons use **neurotransmitters** to transmit their signal across a synapse to other neurons. Dopamine, acetylcholine, epinephrine, and serotonin are examples of neurotransmitters. These chemicals take the electrically conducted signal from one nerve cell (a neuron) and relay it to the next cell (either another neuron or a target cell such as a muscle fiber) (**FIGURE 19-5**).

It is important to remember that nerve cells respond in an all-or-nothing fashion. They either fire or they do not; a neuron cannot fire weakly.

This review has touched on highlights of the various portions of the nervous system. **TABLE 19-1** summarizes the structures of the nervous system and their functions.

Pathophysiology

Many different disorders may cause brain dysfunction or other neurologic symptoms and may affect the patient’s level of consciousness (LOC), speech, and voluntary muscle control. The brain is most sensitive to changes in oxygen, glucose, and temperature levels. A substantial change in any one of these three levels will result in a neurologic

FIGURE 19-5 Neuron and synapse. The signal travels from left to right in this diagram: First, the neuron fires and sends a signal along its axon to the axon terminal. Next, the impulse reaches the axon terminal, where neurotransmitters are released and trickle across the synapse. Although neurons have only one axon, they have many dendrites. When the neuron’s dendrites detect these chemicals, the total excitation determines if a signal is sent to the next cell via its axon. Dendrites also release neurotransmitter deactivators, so that a single impulse from the first neuron generates a single response from the second.

© Jones & Bartlett Learning.

TABLE 19-1 Structures and General Functions of the Nervous System		
Major Structure	Subdivision	General Function
Central Nervous System		
Brain	Occipital	• Vision and storage of visual memories
	Parietal	• Sense of touch and texture and storage of tactile memories
	Temporal	• Hearing and smell • Language • Storage of sound and odor memories
	Frontal	• Motor cortex: Voluntary muscle control and storage of spatial memories • Prefrontal cortex: Judgment and prediction of consequences of a person’s actions; abstract intellectual functions
	Limbic system	• Basic emotions • Basic reflexes (such as chewing and swallowing)
	Diencephalon (thalamus)	• Relay center that prioritizes signals to hone in on important messages
Brainstem	Diencephalon (hypothalamus)	• Emotions • Temperature control • Interface with the endocrine system
	Midbrain	• Level of consciousness • Location of the reticular activating system, which controls arousal and consciousness • Muscle tone and posture
	Pons	• Respiratory pattern and depth
	Medulla oblongata	• Pulse rate; blood pressure; respiratory rate

Major Structure	Subdivision	General Function
Spinal cord	Not applicable	• Reflexes • Relays information to and from body
Peripheral Nervous System		
Cranial nerves	Not applicable	• Special peripheral nerves that connect directly from the brain to body parts to relay information from the brain
Peripheral nerves	Not applicable	• Brain to spinal cord to body part • Receive stimulus from body; send commands to body
Central Nervous System and Peripheral Nervous System		
Neuron	Cell body	• Portion of the neuron where the nucleus resides; site of protein synthesis
	Axon	• Projection from the cell body that reaches out to connect with other neurons or target organs; signals are sent away from the cell body • Some axons are covered with insulation called myelin; myelin increases speed of nerve conduction
	Dendrite	• Projections from cell body that receives signals from axons of other neurons; most neurons have multiple dendrites
	Synapse	• The gap between an axon and a dendrite
	Neurotransmitter	• A chemical released into a synapse that helps make the connection between one neuron and another (eg, serotonin, dopamine, epinephrine)

Data from Bailey R. Neurons. About.com website. <http://biology.about.com/od/humananatomybiology/ss/neurons.htm>. Updated December 15, 2016. Accessed January 8, 2017.

change. In general, if the problem is caused primarily by disorders in the heart and lungs, the entire brain will be affected. For example, when blood flow is stopped (cardiac arrest), the patient will go into a **coma**, a state of profound unresponsiveness, and permanent brain damage can result within minutes. However, if the primary problem is in the brain, such as a poor blood supply to one side of the brain, the patient may have signs and symptoms affecting only one side of the body. A low oxygen level in the bloodstream will affect the entire brain, often causing anxiety, restlessness, and confusion. Extremely low blood glucose levels (hypoglycemia) can cause a wide spectrum of symptoms ranging from mild confusion to symptoms that mimic stroke.

Other brain disorders include conditions such as infection and tumor. Although not all specific problems are addressed, the seizures or altered mental status that often accompanies them is discussed. The information in this section will help you better understand, communicate with, and

care for patients who have experienced some type of brain disorder.

Stroke

A stroke, or **cerebrovascular accident (CVA)**, is an interruption of blood flow to the brain that often is sudden and results in the loss of function in the affected part of the brain. People older than 65 years represent almost 75% of all patients who have experienced stroke.⁴ The American Heart Association (AHA) reports that a substantial number of patients who experience strokes either deny their symptoms or do not understand what their symptoms mean.⁵ Many patients fail to activate emergency medical services (EMS) and subsequently delay care. The goal of treatment, as recommended by the AHA, is early recognition and rapid, appropriate intervention. The longer the stroke continues, the less likely the patient will have a promising outcome because “time is brain.” Early recognition begins with an EMS system that can effectively identify

potential strokes at dispatch and rapidly request the appropriate resources. As an EMS provider, do not delay your response to a patient with a potential stroke. According to the AHA, one-fifth of patients with an intracranial hemorrhage will have a substantial decrease in their LOC between emergency medical care provided by EMS and care on transfer to the emergency department.

Without oxygen, brain cells cease to function and begin to die. These dead cells are called **infarcted cells**. After the cells are infarcted, medical science has little to offer. However, because cell death is not immediate and may take several hours or more to occur, infarction may be prevented with prompt care that leads to restoration of blood flow to the affected cells. Alternately, if a small amount of blood is still able to reach the affected area of the brain, it may supply enough oxygen to keep a larger group of brain cells, called **ischemic cells**, alive, but not enough to let the cells function properly and may result in temporary or permanent disability. If normal blood flow is restored to an ischemic area of the brain in a timely manner, the patient may have less residual damage.

Words of Wisdom

A stroke is also called a “brain attack.” This phrase is used with the general public to emphasize that rapid recognition of the signs and symptoms and prompt transport to an appropriate facility can mean the difference between the patient regaining function and suffering lifelong disability.

Interruption of cerebral blood flow may result from a **thrombus**, a clot that has developed locally, in this case, in a cerebral artery; an **arterial rupture**, a rupture of a cerebral artery; or a **cerebral embolism**, an obstruction of a cerebral artery caused by a clot that was formed elsewhere, detached, and traveled to the brain. Patients with atrial fibrillation are particularly susceptible to ischemic strokes caused by an embolus because there is no organized pumping function in the atria, allowing blood to pool and clot. These patients are often on blood thinners to prevent clots from forming.

The two basic types of stroke are **hemorrhagic stroke** (from arterial rupture) which accounts for 13% of all strokes according to the AHA, and **ischemic stroke** (from an embolism or thrombus),

FIGURE 19-6 Symptom patterns for hemorrhagic stroke compared with ischemic stroke.

© Jones & Bartlett Learning.

which accounts for 87%.⁶ These two causes of strokes have differing presentation patterns, but ultimately, advanced radiographic imaging such as computed tomographic (CT) scanning in a hospital is necessary to differentiate them. The graph shown in **FIGURE 19-6** provides some insight into the evolution of a stroke.

Ischemic Stroke

In an ischemic stroke, a blood vessel is blocked so the tissue distal to the blockage becomes ischemic. Eventually, that tissue will die if blood flow is not restored. But this pathology is self-limiting. Only the tissue beyond the blockage is affected, so the area or areas of the brain involved are limited. This blockage can be from a thrombus or an embolism that obstructs blood flow.

As with coronary artery disease, atherosclerosis in the blood vessels is usually the cause of stroke. **Atherosclerosis** is a disorder in which calcium and cholesterol build up, forming a plaque inside the walls of blood vessels. This plaque obstructs blood flow, interfering with the vessels' ability to dilate. Eventually, atherosclerosis can cause complete occlusion (blockage) of an artery (**FIGURE 19-7**). In other cases, an atherosclerotic plaque in a carotid artery will rupture or crack. A blood clot will form over the disruption in the plaque, sometimes growing big enough to completely block all blood flow through that artery.

Deprived of oxygen, the parts of the brain supplied by the artery will become ischemic. As oxygen and glucose levels drop, brain cells turn to anaerobic metabolism to stay alive. This mechanism, however, is only a stopgap measure. Anaerobic

FIGURE 19-7 Atherosclerosis can damage the wall of a cerebral artery, producing narrowing or a clot. When the vessel is narrowed or completely blocked, blood flow to that part of the brain may be blocked, and the cells begin to die.

© Jones & Bartlett Learning.

metabolism creates only miniscule amounts of energy for the cell and produces acidic by-products. If circulation is not returned quickly, the cell will not have enough fuel to survive and will die.

If the blockage in the carotid artery is incomplete, smaller pieces of the clot may embolize (break off and be carried by the normal flow of blood) deep into the brain. There, a piece of clot may become lodged in a smaller branch of a blood vessel. This cerebral embolism then obstructs blood flow (**FIGURE 19-8**). Depending on the location of the obstruction, the patient's symptoms can vary widely, from nothing at all to an inability to move one side of the body or complete paralysis.

Patients with ischemic strokes will have dramatic symptoms, including, among others, loss of movement on the opposite side of the body, confusion, and the inability to speak.

Hemorrhagic Stroke

A hemorrhagic stroke occurs as a result of bleeding within the brain, typically when a blood vessel ruptures and the accumulated blood then forms a blood clot. The severity of the hemorrhagic stroke depends on the location and size of the ruptured cerebral vessel. As bleeding continues within the brain, **intracranial pressure (ICP)** increases and compresses brain tissue. When brain tissue is compressed, oxygenated blood cannot get into the area, and the surrounding cells begin to die.

FIGURE 19-8 An embolus, a blood clot usually formed on a diseased heart valve, can travel through the body's vascular system, lodge in a cerebral artery, and cause a stroke.

© Jones & Bartlett Learning.

Certain patients are at higher risk for hemorrhagic stroke. The patients at highest risk are those who have chronic, poorly controlled hypertension. Many years of high blood pressure weaken the blood vessels in the brain, making them susceptible to rupture. Cerebral hemorrhages are often fatal, although proper treatment of high blood pressure can help to prevent this long-term damage to the blood vessels, reducing morbidity and mortality.

Arterial walls consist of three layers of tissue. People who are born with a weakness in one or more of those layers are also at increased risk for hemorrhagic stroke. Aneurysms occur in the following way:

1. A small tear or defect occurs within the wall of an artery.
2. Blood penetrates between the layers of the artery.
3. Pressure builds up, and the initial small tear increases in size.

If this process continues, the arterial wall will become so damaged that it can no longer withstand the normal pressure of blood flowing through the artery. The weakened wall will begin to bulge. If the damage is severe, the bulging artery can leak or fail catastrophically, causing an intracranial hemorrhage.

Many people with a hemorrhagic stroke due to a ruptured aneurysm have a sudden onset of a

severe headache, frequently described as “the worst headache of my life,” which signals the rupture of the aneurysm. Shortly after experiencing the severe headache, it is common for the patient’s LOC to decrease rapidly, indicating increased ICP. When a hemorrhagic stroke occurs in an otherwise healthy young person, it is often the result of a saccular aneurysm. This type of aneurysm resembles a tiny balloon (or sac) that protrudes from a cerebral artery. When the aneurysm is overstretched and ruptures, bleeding occurs in the subarachnoid space—the area between the coverings (meninges) of the brain. These types of strokes are therefore called subarachnoid hemorrhages. With prompt care, surgical repair of the aneurysm is sometimes possible. Continued bleeding within the brain will cause the ICP to increase further, thus decreasing cerebral perfusion pressure (CPP). Eventually, the brain, which is substantially compressed, may be forced out of the cranial vault through the foramen magnum in a process called **herniation** (the movement of a structure from its normal location into another space). With herniation, pressure on the medulla oblongata (located directly above the spinal cord) can result in rather bizarre vital signs and other findings, including slowed heart and erratic respiratory rates, eventually leading to death.

Intracranial Pressure

Hemorrhagic strokes that cause bleeding into the brain place patients at risk for increased ICP. Treatment is directed at providing some degree of control over this potentially deadly effect.

The skull (cranial vault) is filled with three substances: brain, blood, and cerebrospinal fluid. These three substances exert a pressure against the skull and the skull exerts a reflected pressure. This balanced exchange allows the brain to fit snugly within the skull without permitting any voids. If the skull contained empty spaces, with head movement, the brain would slam into the skull and cause damage.

When the pressure within the cranial vault begins to increase and remains high (increased ICP), the amount of blood available to the brain decreases. CPP, the pressure of blood within the cranial vault, then begins to fall.

As with most readings within the body, ICP changes constantly. For example, coughing, vomiting, or bearing down tends to increase the ICP.

FIGURE 19-9 Normal and abnormal intracranial pressure.

(Abbreviation: CSF, cerebrospinal fluid)

© Jones & Bartlett Learning.

These momentary spikes in ICP are not harmful. By contrast, if there is blood, swelling, pus, or a tumor within the cranial vault, the ICP will increase and remain high. Because the volume of the cranial vault is limited and inflexible, pressure increases as more substances squeeze into this space. As long as there is no substantial decrease in blood pressure (**FIGURE 19-9**) or significant increase in ICP, the heart will still be able to get blood into the brain. However, patients can have life-threatening issues when ICP rises sharply and/or blood pressure becomes critically low.

As the ICP rises, it creates two major problems. The brain may become ischemic because of a lack of blood supply and/or herniate (push through the ligaments that compartmentalize the brain).

Herniation is a shift of the intracranial contents within the cranial vault or displacement of the contents away from their normal position inside the skull.⁷ Herniation may occur through the foramen magnum, the large opening at the inferior portion of the skull through which the spinal cord exits, or between spaces inside the skull such as the tentorium (a horizontal projection of the dura that separates the cerebellum from the cerebrum). A herniation will eventually compress and strangle the brainstem, at which point the patient will lose control of the vegetative functions. Prehospital treatment is not very effective at decreasing ICP and preventing or reversing herniation.

Documentation and Communication

Patients with strokes can present with a wide range of communication difficulties.

- Patients who are multilingual may lose understanding of one language but not another.
- Patients may be able to understand the written word but not the spoken word.
- Patients may not be able to understand any form of communication.

Be open to trying various ways to communicate. Remember, communication problems do not indicate that the patient is not thinking. The problem is that the patient cannot get you to understand their thoughts.

Transient Ischemic Attack

In some patients, normal processes in the body will destroy a blood clot in the brain. When that happens quickly, blood flow is restored to the affected area, and the patient will regain use of the affected region of the body. When stroke symptoms subside within 24 hours, the event is called a **transient ischemic attack (TIA)**, also referred to as a “small stroke” or a “ministroke.”

No residual damage to brain tissue occurs, and no signs and symptoms appear after the episode ends. However, these ministrokes are often signs of a serious vascular condition that requires medical evaluation. The National Institute of Neurological Disorders and Stroke reports that approximately one-third of patients with TIAs will have an acute stroke sometime in the future.⁸ Think of the relationship between TIA and stroke as the equivalent of the relationship between angina and myocardial infarction.

Although most patients with TIAs do well, it is still a neurologic emergency. For this reason, all patients with a TIA should be evaluated by a physician to determine whether action can be taken to prevent a stroke in the future.

Signs and Symptoms of Stroke

The general signs and symptoms of stroke include the following:

- Facial drooping
- Sudden weakness or numbness in the face, arm, leg, or one side of the body

- Decreased or absent movement and sensation on one side of the body
- **Ataxia** (lack of muscle coordination) or loss of balance
- Sudden vision loss in one eye; blurred or double vision (diplopia)
- **Dysphagia** (difficulty swallowing)
- Decreased level of responsiveness
- Aphasia; difficulty expressing thoughts or inability to use the right words (expressive aphasia) or difficulty understanding spoken words (receptive aphasia)
- Slurred speech (dysarthria)
- Sudden and severe headache
- Confusion
- Dizziness
- Weakness
- Combativeness
- Restlessness
- Tongue deviation
- Coma

Left Hemisphere Problems

If the left cerebral hemisphere has been affected by a stroke, the patient may exhibit a speech disorder called **aphasia**, the inability to produce or understand speech. Speech problems vary widely. Patients may have trouble understanding speech but can speak clearly. This condition is called receptive aphasia. You can detect aphasia by asking the patient a question such as “What day is today?” In response, a patient with aphasia may say, “Green.” The speech is clear, but the answer does not make sense. Other patients will be able to understand the question but cannot produce the right sounds to provide an answer. Only grunts or other incomprehensible sounds emerge. This type of aphasia is expressive. Strokes that affect the left side of the brain also can cause paralysis on the right side of the body and vice versa.

Right Hemisphere Problems

If the right cerebral hemisphere of the brain is not getting enough blood, patients will have trouble moving the muscles on the left side of the body. Usually, they will understand language and be able to speak, but their words may be slurred and difficult to understand. Slurred speech is one characteristic of **dysarthria**.

It is interesting that patients with right hemisphere strokes may be completely oblivious to their problem. If you ask the patients to lift the left arm and they cannot, they will lift the right arm instead. They seem to have forgotten that the left arm even exists. This symptom is called neglect. Patients with a problem affecting the posterior aspect of the cerebrum (occiput) may neglect certain parts of their vision. Generally, this is difficult to detect in the field, but you should be aware of the possibility. Try to sit or stand on the patient's unaffected side, because the person may be unable to see things on the affected side.

Neglect and lack of pain cause many patients who have had large strokes to delay seeking help. Unless caused by a ruptured cerebral artery, in which case the patient will complain of a severe headache, strokes are typically not painful. Therefore, a patient may be unaware that there is a problem until a family member or friend points out that some part of the patient's body is not working correctly.

Bleeding in the Brain

Patients who have bleeding in the brain (intracerebral hemorrhage) may present with hypertension. Sometimes hypertension is the cause of the bleeding but, many times, it is a response to the bleeding; hypertension may be a response of the body to shunt more oxygenated blood to the injured portion of the brain. Remember, the brain is located inside a box (skull) with only a few openings. When bleeding occurs inside the brain, the pressure inside the skull increases. The body must increase the blood

pressure to get blood to the brain's tissues, increasing the pressure even further.

High blood pressure in stroke patients should not be treated in the field. Monitoring the blood pressure and watching for a trend of increasing blood pressure is important. Blood pressure may return to normal or decrease substantially on its own. Substantial decreases in blood pressure may also occur as the patient's condition worsens.

Conditions That May Mimic Stroke

The following three conditions may present similarly to stroke:

- **Hypoglycemia** (a condition characterized by a low blood glucose level)
- A **postictal state** (the reset period of the brain after a seizure, lasting between 5 and 30 minutes and characterized by labored respirations and some degree of altered mental status)
- Subdural or epidural bleeding (a collection of blood near the skull that presses on the brain)

Because oxygen and glucose are needed for brain metabolism, a patient with hypoglycemia may look like a patient who is experiencing a stroke. You should check the patient's blood glucose level and find out whether the patient has diabetes and takes insulin or a glucose-lowering medication.

A patient in the postictal state may appear to be experiencing a stroke; however, in most cases, a patient in a postictal state will recover without assistance, whereas a patient experiencing a stroke will not.

Subdural bleeding and epidural bleeding usually occur as results of trauma. The dura is a leathery covering over the brain, next to the skull. A fracture near the temporal region of the skull may cause an artery (usually the middle meningeal artery) to bleed on top of the dura, resulting in pressure on the brain (**FIGURE 19-10A**). Because the source of bleeding is from an artery, the onset of symptoms from epidural bleeding is usually very rapid after the injury. In other cases, the veins just below the dura may be torn and bleed, which is known as subdural bleeding (**FIGURE 19-10B**). Because veins tend to bleed slowly, the onset of symptoms occurs more slowly, sometimes over several days. These conditions are thoroughly discussed in Chapter 30, *Head and Spine Injuries*.

Words of Wisdom

The following is pertinent information to document for a patient who may be experiencing a stroke:

- Time of onset of the signs and symptoms
- Score on the Glasgow Coma Scale (GCS)
- Results of a stroke assessment tool (Cincinnati, Los Angeles, LAG, or BE-FAST)
- Changes noted on reassessment

Establishing the time of onset is critical information because it helps determine whether the patient is a candidate for treatment with fibrinolytic drugs or clot-retrieval therapy.

FIGURE 19-10 Trauma to the head can result in intracranial bleeding. **A.** Bleeding outside the dura but under the skull is epidural. **B.** Bleeding beneath the dura but outside the brain is subdural.

© Jones & Bartlett Learning.

With subdural and epidural bleeding, the onset of strokelike signs and symptoms may be subtle. The patient or family may not even remember the original injury that is causing the bleeding.

Seizures

Seizures are sudden, erratic firings of neurons. Patients who have epilepsy commonly have seizures, for example. Patients can experience a wide array of signs and symptoms when having seizures, such as muscle spasms, increased secretions, diaphoresis, and cyanosis. A seizure can be limited to one hand shaking or a metallic taste in the mouth, or it can involve the movement of every limb or the complete loss of consciousness. Patients may be aware of the seizure or wake up afterward not knowing what happened.

Types of Seizures

Seizures are classified according to where they begin in the brain, the person's level of awareness during the seizure, and any other defining features.

The following discussion broadly groups the types of seizures according to their nature of onset, namely generalized onset (affecting large portions of the brain) or focal onset (affecting a limited area of the brain).

Generalized Seizures

Generalized seizures result from abnormal electrical discharges from large areas of the brain, involving both hemispheres. They are typically characterized by unresponsiveness and a generalized severe twitching of the body's muscles that lasts several minutes or longer; when muscle activity is present, the seizure is further classified as *motor*. In generalized motor seizures (specifically **generalized tonic-clonic seizures**), almost all of the muscles in the body are contracting at the same time, causing twitching or jerking motions. Throughout a generalized tonic-clonic seizure, the patient exhibits tachycardia, hyperventilation, sweating, and intense salivation; however, other responses are also possible.

Most generalized tonic-clonic seizures follow a pattern, traveling through each of the following steps in order, although some patients may not experience every step:

1. **Aura.** A sensation the patient experiences before the seizure occurs (for example, muscle twitch, odd taste, seeing lights, hearing a high-pitched noise)
2. **Loss of responsiveness**
3. **Tonic phase.** Body-wide rigidity
4. **Hypertonic phase.** Arched back and rigidity
5. **Clonic phase.** Rhythmic contractions of major muscle groups; arms, legs, and/or head movement; lip smacking; biting; and teeth clenching. Contractions are chaotic, disorganized, and of small amplitude. Imagine ventricular fibrillation of the brain—that is what a seizure is electrically.
6. **Postseizure.** Major muscles relax; nystagmus (involuntary, rhythmic eye movement) may still occur; eyes possibly rolled back.
7. **Postictal phase.** Reset period of the brain. The reset can take several minutes to hours before the patient gradually returns to the pre-seizure LOC. During this time, patients are often initially aphasic (unable to speak), confused or unable to follow commands, emotional, or

tired and may be incontinent of urine and/or feces. They may present with a headache. Gradually the brain will begin to function normally.

Street Smarts

An aura can include visual changes (flashing lights or blind spots in the field of vision) or hallucinations (seeing, hearing, or smelling things that are not actually present). People with a history of seizures recognize their auras and usually take steps to minimize injury, such as sitting or lying down. Pay attention when patients tell you they are about to have a seizure and position them in preparation. However, be aware that auras do not occur prior to every seizure, and not all patients with a seizure disorder experience an aura.

Generalized tonic-clonic seizures are disconcerting for both family and health care providers to watch. During the seizure process, respiration may become erratic, loud, and obviously abnormal. Alternatively, the patient may stop breathing and become cyanotic. These periods of apnea are usually short lived and do not require intervention. If the patient is apneic for more than 30 seconds, immediately begin ventilatory assistance. Another

disconcerting aspect of seizures, particularly for the patient, is incontinence.

Pseudoseizures, also called psychogenic non-epileptic seizures, are a generalized neurologic event. Symptomatically, you may not notice any difference from a generalized seizure. Tonic-clonic motion, loss of responsiveness, and a postictal phase are all present during these events. The difference is that in pseudoseizures, the root cause is of psychiatric origin. It is important to understand that in most cases of pseudoseizure, the patient is not intentionally causing this behavior.

Patients with pseudoseizures present with loss of responsiveness, which is usually triggered by some emotional event, stress, lights, or pain. Pseudoseizures conspicuously occur with witnesses. This fact may lead health care providers to believe pseudoseizures are contrived. Motion that occurs during the seizure is relatively organized—side-to-side movement of the head, pedaling movements of the legs (such as riding a bicycle), weeping, or stuttering. These patients often have a psychiatric history and/or other medical history, such as fibromyalgia, chronic pain, or chronic fatigue.

Absence seizures (also known as generalized nonmotor seizures) present with little or no movement. The seizure may simply be characterized by

YOU are the Provider

Part 2

Realizing that this call is not just a “normal” intoxication, you conduct a Cincinnati Prehospital Stroke Scale screening. The patient fails all tests. Per your protocols, you ask your partner to call the local hospital, which has a stroke team, to advise them that you have a “stroke alert” patient. You and a shelter worker assist the patient onto a stretcher, and you quickly obtain a set of vital signs. The worker states that he saw the patient maybe 20 or 30 minutes ago and he was acting normal at that time.

Recording Time: 1 Minute

Appearance	Slurred speech, right-side facial droop, and possible left-side weakness
LOC	Alert and confused
Airway	Patent
Breathing	12 breaths/min
Circulation	Strong radial pulse; skin is warm and dry

- What are the two types of strokes that this patient may be experiencing?
- Should you move the patient into the back of the ambulance for evaluation?

a brief lapse of responsiveness in which the patient seems to stare and not to respond to anyone. The typical patient with absence seizures is a child. Classically, the child will simply stop moving; the child may be walking and just stop, may be speaking and stop midsentence, or may be playing and freeze with a toy in the hand. The child will rarely fall. These seizures usually last no more than several seconds. There is no postictal period and no confusion. These may be brought on by flashing lights or hyperventilation.

Focal Seizures

Focal seizures start in one area of the brain. Focal-onset seizures are classified as either aware or impaired-awareness, and either type can be motor or nonmotor (absence). In a focal-onset, aware seizure, no change occurs in the patient's level of responsiveness. Patients may report numbness, weakness, or dizziness. The senses may also be involved; the patient may report visual changes and unusual smells or tastes. A focal-onset aware (motor) seizure may also cause twitching of the muscles and the extremities that may spread slowly from one part of the body to another, but it is not characterized by the dramatic severe twitching and muscle movements seen in a generalized tonic-clonic seizure. The patient may also experience brief paralysis.

In a focal-onset, impaired-awareness seizure, the patient has an altered mental status and does not interact normally with the environment. This type of seizure results from abnormal discharges from the temporal lobe of the brain. Other signs may include lip smacking, eye blinking, and isolated convulsions or jerking of the body or one part of the body, such as an arm. The patient may experience unpleasant smells and visual hallucinations, exhibit uncontrollable fear, or exhibit repetitive physical behavior such as constant sitting and standing. In impaired-awareness seizures, the patient usually does not remember events occurring during the seizure.

Some focal-onset seizures remain on only one side of the body. Others begin on one side and gradually progress to the entire body. In focal-onset, aware seizures, the patient may have no loss of responsiveness but still experience body shaking or muscle tremors. Most people with lifelong or chronic seizures tolerate these events reasonably well without complications, but in some patients, seizures may signal life-threatening conditions.

Words of Wisdom

Always assess blood glucose levels for any patient with an altered mental status and especially those who have had seizures. Although hypoglycemia may result in seizure activity, it is also important to remember that the muscular activity involved in a generalized tonic-clonic seizure may rapidly decrease glucose stores. A patient who was not hypoglycemic at the onset may become hypoglycemic as a result of the seizure activity.

Status Epilepticus

Status epilepticus is a seizure that lasts for longer than 4 or 5 minutes or consecutive seizures that occur without the return of responsiveness between seizure episodes. This time frame is arbitrary, however, and some authors suggest that status epilepticus does not occur until 30 minutes of uninterrupted seizure activity. Refer to your local protocols for guidelines on how long a seizure can continue before you should intervene. Status epilepticus is a life-threatening neurologic disorder and it should not be taken lightly. The authors of a 2015 study reported that the mortality rate for patients in refractory status epilepticus was 70%.⁹

During a seizure, neurons are in a hypermetabolic state (using large amounts of glucose and producing lactic acid). For a short period, this state does not produce long-term damage. If the seizure continues, then the body becomes unable to remove waste products effectively or ensure adequate glucose supplies. Such a hypermetabolic state can result in neurons being damaged or killed. The goals of prehospital care are to stop the seizure and ensure adequate ABCs (airway, breathing, and circulation), including adequate glucose levels.

Special Populations

Status epilepticus is harmful at any age, but because of physical changes caused by the normal aging process, geriatric patients are at greater risk of hypoxia, hypotension, and/or cardiac dysrhythmias.

Causes of Seizures

There are various reasons why a patient may have a seizure, ranging from a congenital disorder, to a

diabetic emergency, to fever (a possible cause if the patient is an infant). Knowing the cause will help direct management.

Some seizure disorders, such as epilepsy, are congenital, which means that the patient was born with the condition. Other types of seizures may be a result of a high fever, structural problems in the brain, or metabolic or chemical problems in the body (**TABLE 19-2**). Epileptic seizures can usually be controlled with medications such as phenytoin (Dilantin), phenobarbital (Solfoton), carbamazepine (Tegretol), levetiracetam (Keppra), gabapentin (Gabarone, Neurontin), valproate (Depakote), topiramate (Topamax), or lamotrigine (Lamictal). Patients with epilepsy often have seizures if they stop taking their medications or if they do not take the prescribed dose on a regular basis. In fact, most seizures are the result of medication non-compliance. In the emergency department, blood analysis will frequently show a subtherapeutic level of the antiepileptic drug.

Seizures can also result from sudden high fevers, particularly in infants and small children. Such seizures, known as **febrile seizures**, are usually unnerving for parents to observe but are generally well tolerated by the child unless they are prolonged. Nevertheless, you must transport a child who has

had a febrile seizure because this condition needs to be evaluated in the hospital. It is possible a second seizure may occur. If it does, the patient requires rapid evaluation in a hospital to identify possible causes, such as serious inflammation in the brain or tissues covering the brain (conditions known as encephalitis and meningitis, respectively; an abscess may also be present). Febrile seizures result from a rapid increase in body temperature. In other words, it is not necessarily how high the fever gets, but how quickly it gets there.

Words of Wisdom

Use the mnemonic FACTS to obtain pertinent history for patients having a seizure:

- F**ocus (Generalized or focal?)
- A**ctivity (Type of movements?)
- C**olor or **C**ocaine (Cyanosis? Indications of cocaine use?)
- T**ime (How long did the seizure last?)
- S**econdary information (Medications? Events leading up to the seizure? Incontinence? Tongue biting?)

TABLE 19-2 Common Causes of Seizures

- Abscess
- Alcohol
- Birth anomaly
- Brain infections (meningitis, encephalitis)
- Brain trauma
- Diabetes mellitus (hypoglycemia)
- Fever (rapid rate of rise)
- Hypertension during pregnancy (eclampsia)
- Hypoxia
- **Idiopathic** (of no known cause)
- Inappropriate medication dosage
- Organic brain syndromes
- Poisoning
- Recreational drug use (cocaine)
- Stroke or TIA
- Sudden withdrawal from alcohol or medications
- Systemic infection (sepsis)
- Tumor
- **Uremia** (kidney failure)

Abbreviation: TIA, transient ischemic attack

© Jones & Bartlett Learning.

The Importance of Recognizing Seizures

Regardless of the type or cause of a seizure, it is extremely important for you to recognize when a seizure is occurring or whether one has already occurred. You must also determine whether this episode differs from any previous ones. For example, if a previous seizure occurred on only one side of the body and this seizure occurred over the entire body, some additional or new problem may be involved. In addition to recognizing that seizure activity has occurred and/or that something different may now be occurring, you must also recognize the postictal state and the complications of seizures.

Because most seizures involve vigorous twitching of the muscles, the muscles use a lot of oxygen. This excessive demand consumes oxygen that was being delivered by the circulation to support the vital functions of the body. A seizure is similar to a situation in which you exercise vigorously without giving your body a chance to rest. As a result, there is a buildup of acids in the bloodstream, and the patient may turn cyanotic (blue lips, mucous

membranes, and skin) from the lack of oxygen. Often the seizures themselves prevent the patient from breathing normally, making the problem worse. In a patient with diabetes, the blood glucose level may decrease because of the excessive muscular contraction of a seizure. If your local protocol allows, closely monitor the blood glucose level after a patient with diabetes has a seizure.

Recognizing seizure activity also means looking at other problems associated with the seizure. For example, the patient may have fallen during the seizure episode and injured some part of the body; head injury is the most serious possibility. Patients having a generalized tonic-clonic seizure may experience **incontinence**, meaning that they may lose bowel and bladder control. Therefore, one clue that unresponsive or confused patients may have had a seizure is to find that they were incontinent. Although incontinence is possible with other medical conditions, sudden incontinence is likely a sign that a seizure has occurred.

Safety

Be aware that patients may behave violently during the postictal phase. They might not know what has happened and might be frightened by “strangers” providing care or trying to move them into the ambulance. Alcohol and/or drugs are not always associated with violent behavior during the postictal phase, but signs of their use or abuse should heighten your awareness of the potential for dangerous behavior.

The Postictal State

After a seizure has stopped, the patient’s muscles relax, becoming almost flaccid, or floppy, and breathing becomes labored (fast and deep) in an attempt to compensate for the buildup of acids in the bloodstream. By breathing faster and more deeply, the body can balance the pH in the bloodstream. With normal circulation and liver function, the acids clear away within minutes, and the patient will begin to breathe normally. The longer and more intense the seizure was, the longer it will take for this imbalance to correct itself. Similarly, longer and more severe seizures will result in a longer postictal phase.

In some situations, the postictal state may be characterized by **hemiparesis**, or weakness on one side of the body, resembling a stroke. Unlike the typical stroke, hypoxic hemiparesis spontaneously resolves within a short period. Most commonly, the postictal state is characterized by lethargy and confusion to the point that the patient may be combative and appear angry. You must be prepared for these circumstances in your approach to scene control and in your treatment of the patient’s symptoms. If the patient’s condition does not improve, you should consider other possible underlying problems, including hypoglycemia and infection.

Words of Wisdom

Physician evaluation of a patient who has had a seizure depends heavily on reports of the seizure pattern and changes in that pattern. For example, was this seizure different from previous ones? If so, how? Record all pertinent information about the seizure in terms of duration, areas of body movement, and possible precipitating factors (such as recent trauma, fever, and medication noncompliance). Effective interviewing of available witnesses, family members, or caregivers is needed to obtain the required information.

Altered Mental Status

Aside from stroke and seizures, the most common type of neurologic emergency that you will encounter is a patient with altered mental status. Simply put, altered mental status means that the patient is not thinking clearly or is incapable of being aroused. In some cases, patients will be unresponsive (**FIGURE 19-11**); in others, they may be responsive but confused. The range of problems is wide, and the causes are many, including common problems such as hypoglycemia, hypoxemia, intoxication, drug overdose, unrecognized head injury, brain infection, body temperature abnormalities; and uncommon conditions such as brain tumors, glandular abnormalities, and overdoses and/or poisonings.

Hypoglycemia

The clinical picture of patients with altered mental status caused by hypoglycemia is complex. Because

FIGURE 19-11 A patient with altered mental status can be unresponsive in some cases; in others, the patient may be responsive but confused.

© Jones & Bartlett Learning.

FIGURE 19-12 During your assessment of a patient with an altered or decreased level of consciousness, consider the possibility of hypoglycemia and check the patient's blood glucose level.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

oxygen and glucose are needed for brain function, hypoglycemia can mimic the signs and symptoms of stroke and seizures. Patients may have hemiparesis, similar to what occurs as a result of a stroke. However, the principal difference is that a patient who has experienced a stroke may be alert and attempting to communicate normally, whereas a patient with hypoglycemia almost always has an altered mental status (**FIGURE 19-12**).

Patients with hypoglycemia commonly, but not always, take medications that lower the blood glucose level. Therefore, if the patient appears to have signs and symptoms of stroke and an altered mental

status, you should report your findings to medical control and treat the patient accordingly. Check for and report medications, but remember that not all patients who have diabetes take insulin or other medications to lower the blood glucose level. Remember, also, that patients with a decreased LOC may not be able to adequately protect their airways, in which case they should not be given anything by mouth. Local protocols should guide your actions.

Patients with hypoglycemia can also experience seizures, and you may arrive at the scene to find a patient in a postictal state: confused and disoriented or unresponsive. The mental status of a patient who has had a typical seizure is likely to improve soon after the seizure stops; however, in a patient with hypoglycemia, the mental status is not likely to improve, even after several minutes. Therefore, you should consider the possibility of hypoglycemia in a patient who has had a seizure, especially if the blood glucose reading is low.

Similarly, you should consider hypoglycemia in a patient who has altered mental status after an injury such as a motor vehicle crash, even when there is the possibility of an accompanying head injury. As with any other patient, you should look for medical identification bracelets or medications that might confirm your suspicions.

Other Causes of Altered Mental Status

In addition to hypoglycemia, three other possible causes of altered mental status include hypoxia (regardless of the cause), unrecognized head injury, and severe alcohol or drug intoxication. Your consideration of these and other possibilities becomes important because a patient with altered mental status may be combative and refuse treatment and transport. You should be prepared for difficult patient encounters and follow local protocols for dealing with these situations, recognizing the potential for serious underlying problems.

In most cases, a patient who appears intoxicated is just that; however, the patient might have other problems as well. People with alcoholism can have abnormalities in liver function, blood clotting, and the immune system, which can predispose them to intracranial bleeding, brain and bloodstream infections, and hypoglycemia.

Psychological problems and adverse effects of medications are also possible causes of altered mental status. In addition, a person who appears

to have a psychological problem may also have an underlying medical condition.

Infections are another possible cause, particularly those involving the brain or bloodstream. Infections in these areas are life threatening and need immediate attention. Patients may not demonstrate typical signs of infection, such as fever, particularly if they are very young or very old or have an impaired immune system.

Altered mental status can also be caused by drug overdose and poisonings; therefore, you should monitor patients closely for accompanying cardiac and respiratory problems.

The presentation of altered mental status varies widely from simple confusion to coma. Regardless of the cause, you should consider altered mental status to be an emergency that requires immediate attention, even when it appears that the culprit may be alcohol intoxication or a minor car crash or fall.

Syncope

Syncope (fainting) is the sudden and temporary loss of consciousness with accompanying loss of postural tone. Syncope can be a sign of life-threatening cardiac dysrhythmia, stroke, or other serious medical condition. It affects mainly adults and accounts for 1% to 3% of all emergency department visits.¹⁰ The brain uses glucose at a high rate and has no ability to store glucose, so even a 3- to 5-second interruption in blood flow can cause loss of consciousness. The question then becomes: “What caused the sudden decrease in cerebral perfusion?” Potential causes include problems with cardiac rhythm or conduction, problems with cardiac muscle, myocardial infarction, dehydration, hypoglycemia, and a vasovagal episode.

Headache

One of the most common complaints of pain you will hear from your patients is headache. Because a headache is subjective, it may be a symptom of another condition or it may be considered a neurologic condition on its own. Millions of people experience a headache every year, but only a small percentage of these are caused by a serious medical condition. The brain and skull do not actually sense pain because neither contains pain receptors. The pain associated with a headache is felt from the surrounding areas of the face; scalp, meninges (membranes that cover the

brain and spinal cord); larger blood vessels; and the muscles of the head, neck, and face.

Tension headaches, migraines, and sinus headaches are the most common types of headaches and are not considered life threatening, although they may be debilitating for the patient. Tension headaches may be caused by stress, altered cortisol levels, and/or depression, which causes residual muscle contractions (tension) within the face and head. The jaw, neck, or shoulders may be stiff or sore. Patients usually describe the pain as squeezing or dull or as an ache. This type of headache does not have any associated symptoms and usually does not require medical attention.

A migraine headache is a complex condition thought to be caused by minor instability within certain clusters of neurons, and also by changes in blood vessel size at the base of the brain. The patient may experience an aura (for example, seeing bright lights) and unilateral, focused pain that then spreads over time. The patient often describes the pain as throbbing, pounding, or pulsating and may have nausea or vomiting. During a migraine headache, patients prefer dark, quiet environments. Migraines can last several days.

Two other types of headaches are cluster headaches and sinus headaches. Cluster headaches are rare vascular headaches that occur in groups, or clusters, and last 30 to 45 minutes. However, a person may have several cluster headaches per day. The headaches can recur for days and then stop entirely. They may return at the same time the following month or the same time the next day. The pattern consists of minor pain around one eye. The pain—described as sharp and excruciating, or as if someone is pushing the eyeball out—quickly intensifies and spreads to one side of the face and causes a feeling of anxiety. Sinus headaches are caused by inflammation or infection within the sinus cavities of the face. The pain is located in the superior portions of the face and increases with bending the head forward.

Patient Assessment

The brain is the organ that is most sensitive to fluctuating levels of oxygen, glucose, and temperature; it responds to alterations in these levels with changes in its function. The brain is relatively resilient to internal environmental changes: it does not

simply shut down when the oxygen level falls. The key to identifying a neurologic problem is to look for obvious changes and subtle changes.

Scene Size-up

Remember to take standard precautions. A patient having a generalized tonic-clonic seizure, for example, may be incontinent.

Patients with altered levels of consciousness or who are combative may require additional assistance with lifting and moving. Request additional resources early in the call, and ensure you have a way to remove yourself from the scene if needed.

Look for clues at the scene as to what may have happened: for example, an overturned table with blood on the corner indicating where a patient fell. Information from the scene size-up is key to the hospital staff who will be caring for the patient.

As always, consider the need for spinal precautions based on dispatch information and your

assessment of the scene as you approach the patient.

Consider the mechanism of injury (MOI) or history of present illness. Look for signs of potential trauma (the MOI), indications of a previous medical condition such as diabetic supplies or medical alert tags, and evidence of a seizure. Did anyone witness what happened? When was the last time anyone saw the patient appearing healthy? Most patients with a neurologic emergency have a change in their LOC and their ability to interact with their environment and others.

The AEIOU-TIPS mnemonic is helpful for remembering causes of a decreased LOC. When assessing a patient with an altered mental status, consider these causes (**TABLE 19-3**).

Examine the scene to ascertain the number of patients. One patient with a headache does not stand out. If an entire family in the same house complains of headache, consider the possibility of carbon monoxide exposure. In such a case, the scene may be unsafe.

TABLE 19-3 AEIOU-TIPS: Altered Mental Status Causes

Letter	Name	Signs and Symptoms
A	Alcohol	Intoxication; slurred speech; ataxia; odor of alcohol on breath; tremors; hallucinations
	Acidosis	Multiple causes; tachypnea and hyperpnea are common
E	Epilepsy (seizure)	Aura; hypertonic, tonic-clonic activity; postictal state
	Endocrine	For thyroid conditions, increased metabolism (hyperthermia, hypertension, tachypnea, tachycardia) OR decreased metabolism (hypothermia, bradycardia, bradypnea, and hypotension)
	Electrolytes	Dehydration; renal failure; liver failure; ECG changes, etc.
I	Insulin	Diaphoresis; tachycardia; tremors; ataxia
O	Opiates	Constricted pupils; decreased LOC; bradypnea; cyanosis
	Other drugs	Varies depending on agent involved; track marks; drug paraphernalia
U	Uremia (kidney failure)	Nausea/vomiting; uremic frost; muscle cramping; dysrhythmias; pulmonary edema
T	Trauma	Generally, hypotension causes altered LOC or direct head injury.
	Temperature	Hyperthermia (exertional, environmental, or endocrine); hypothermia (environmental, endocrine, situational [eg, immobile person lying on floor for days])
I	Infection	Fever; rash; malaise; tachycardia; tachypnea; skin may be cold or warm depending on degree of infection

Letter	Name	Signs and Symptoms
P	Poisoning	Varies depending on agent involved; empty pill bottles; chemical odors within a child's mouth; broken leaves of plants, open containers of pesticide
	Psychogenic causes	Delusions; hallucinations; disorganization; bizarre behavior or posture
S	Shock	Decreased blood pressure and other signs of poor perfusion
	Stroke	Facial droop; slurred speech; ataxia; abnormal/irregular respiratory pattern; potential bradycardia
	Syncope	Prodrome of weakness or loss of peripheral vision, then LOC which resolves quickly.
	Space-occupying lesion	Headache; new onset seizures; strokelike symptoms
	Subarachnoid hemorrhage	Thunderclap headache; worst headache of life; signs and symptoms of stroke; seizures

Abbreviations: ECG, electrocardiogram; LOC, level of consciousness

© Jones & Bartlett Learning.

Finally, if the time it takes to get to the nearest stroke center is greater than 1 hour, then request air medical transport early if available.

Primary Survey

As you approach the patient, note the patient's body position and LOC. Observe for seizure activity. Most seizures will be over by the time you arrive. If the seizure is still occurring, the potentially life-threatening condition of status epilepticus may be present. A patient in a postictal state may be unresponsive or starting to regain awareness of the surroundings. Determining the patient's LOC should be first course of action.

If the patient does not respond to verbal stimuli, consider whether the patient may be displaying abnormal posturing; this may indicate severe brain dysfunction. There are two main abnormal postures that the patient may demonstrate with painful stimulation—decorticate and decerebrate. If you see either posture, you should immediately consider the patient to be in critical condition, because these postures represent substantial ICP.

In **decorticate posturing** (abnormal flexion), the patient contracts the arms and curls them toward the chest, the toes are pointed, and the wrists are flexed. This posture may indicate damage to the area directly below the cerebral hemispheres (**FIGURE 19-13**). You can easily remember

FIGURE 19-13 Decorticate posturing (abnormal flexion).

Courtesy of Chuck Sowerbrower, MED, NREMT-P.

FIGURE 19-14 Decerebrate posturing (extension).

Courtesy of Chuck Sowerbrower, MED, NREMT-P.

the meaning because with decorticate posturing, the patient's hands are flexed toward the core. In **decerebrate posturing** (extension), the patient again points the toes, but now extends the arms outward and rotates the lower arms in a palms-down manner (**pronation**). The wrists and hands are again flexed (**FIGURE 19-14**). This posture is a more severe finding than decorticate posturing. In decerebrate

Street Smarts

When caring for patients with neurologic issues such as stroke or seizures, good interpersonal skills are crucial. Compassion and empathy are important in managing these patients. The patient and family may regard the emotional support you provide as more valuable than the physical skills you perform. Your ability to make the patient comfortable and provide reassurance during assessment and transport is essential.

posturing, the level of damage is within or near the brainstem (diencephalon/pons/midbrain).

Focus on the patient's airway and breathing on arrival. If the patient is unresponsive and apneic, immediately assess for a pulse and begin chest compressions if pulseless. Evaluate the airway of an unresponsive patient to make sure it is patent and will remain that way. Patients who have experienced a stroke may have difficulty swallowing and are at risk for choking on their own saliva. Continually reassess the airway for patency and respiratory rate and quality. If the patient requires assistance maintaining an airway, consider an oropharyngeal or nasopharyngeal airway. Provide suction and

position the patient to prevent aspiration. If you determine that the patient cannot protect the airway, place the patient in the recovery position to help prevent secretions from entering the airway.

A patient who has had or is having a seizure may have been eating or chewing gum at the time of the seizure, and there may be a foreign body obstruction. Bystanders may have tried to put objects in the patient's mouth to keep the person from "swallowing the tongue," even though this practice is not advised. A seizure patient may clench their teeth (**trismus**) and require sedation. Call early for paramedic backup if dealing with a difficult airway.

Assess the patient's breathing. Be sure to check the rate and rhythm of breathing. Rhythms can have subtle changes or be dramatically different from normal. Generally, the greater the deviation from normal, the more severely the nervous system is affected.

Standard stroke care includes titrating oxygen therapy to the patient's need. Evaluate the patient's pulse oximetry to maintain an SpO_2 of greater than 94%.⁵ Ensure that your SpO_2 reading is accurate. Use other assessment techniques, such as end-tidal carbon dioxide (ETCO_2), if available and necessary, to ensure your patient is breathing adequately. From

YOU are the Provider

Part 3

After calling the hospital, your partner advises you that medical control has directed you to transport the patient to Miami General Hospital (MGH), approximately 25 minutes away. There is no neurologist on duty at the local hospital today. You inform your partner of the patient's serious condition and proceed to load him into the ambulance. Your partner applies a nonrebreathing mask with oxygen at 15 L/min, while you insert an 18-gauge intravenous (IV) line. After the IV line is secured, you instruct your partner to initiate emergency transport to MGH.

Recording Time: 12 Minutes

Respirations	12 breaths/min
Pulse	Strong and regular; 74 beats/min
Skin	Warm and dry
Blood pressure	246/168 mm Hg
Oxygen saturation (SpO_2)	100% at 15 L/min via nonrebreathing mask
Pupils	Left pupil nonreactive

- What conditions mimicking stroke should AEMTs consider?
- Should this patient receive a bolus of IV fluid?

a respiratory point of view, if the patient is in stable condition, the nasal cannula is probably sufficient.

Unless you are concerned about possible spinal injury, elevate the head 30°. Provide ventilatory support at 10 to 12 breaths/min unless the patient presents with signs of cerebral herniation. Do not increase the rate any higher than 20 breaths/min because hyperventilation will cause vasoconstriction and decrease perfusion to the brain. Do not suction vigorously. Stimulating the cough and gag reflexes will increase ICP.

Assess circulation beginning with the pulse. As mentioned, if no pulse is found, immediately begin cardiopulmonary resuscitation beginning with chest compressions, and attach an automated external defibrillator. If the pulse is present, determine whether it is fast or slow, weak or strong, or if it is bounding. Evaluate the peripheral and central pulse pressures. Are they the same? The absence of a peripheral pulse with a central pulse present should cause you to suspect shock. What are the characteristics of the skin? Do you see evidence of gross bleeding?

Assess vital signs for evidence of increased ICP. With increased ICP, the blood pressure rises, the heart rates decrease, respiratory rates become irregular, and the pulse pressure widens (systolic hypertension). This set of conditions, known as the Cushing reflex, is the opposite of what is expected in shock.

Special Populations

When you are assessing an infant for increased ICP, consider the quality of the cry. As the ICP increases, the pitch of the cry will increase until a shriek similar to that of a cat can be heard. At the same time, the shape of the pupils can change from round to more oval. These two findings lead to the saying related to infants and increased ICP: “cat’s eyes and cat’s cries.”

At this point in the examination, you should make a transport decision. Unstable patients—those with inadequate or deteriorating ABCs or a substantial MOI or nature of illness—should be transported rapidly to the closest, most appropriate facility. Defer gathering detailed information about patients in critical condition; instead, focus on stabilizing and maintaining ABCs. With stable

patients—those with normal primary survey findings and a minor MOI or nature of illness—you have more time to gather detailed information at the scene.

If you suspect the patient is experiencing a stroke, you should rapidly transport the patient to an appropriate facility, preferably a stroke center, to ensure that every chance is available to reduce the disability caused by an ischemic stroke. Fibrinolytic medications, commonly referred to as clot busters, have been shown to reverse symptoms, thus aborting the stroke, if administered within 3 to 4.5 hours after the onset of symptoms for strokes caused by thrombotic or embolic events. Interview family members or bystanders to determine when the patient was last seen “normal” and document the time. Rapid recognition and transport to an appropriate facility may prevent permanent damage and decrease mortality.

Some facilities will need to contact technicians to operate the CT scanners during night hours or weekends; early notification to the emergency department can decrease the time to begin obtaining the scan. If the patient’s condition is rapidly decompensating or you suspect a potential stroke, consider transport to a designated stroke center.

If you suspect the patient may have experienced a stroke, place the patient in a comfortable position, usually on one side, with the paralyzed side down and well protected with padding (FIGURE 19-15). The patient’s head should be elevated approximately 6 inches (15 cm).

FIGURE 19-15 A patient who has experienced a stroke should be positioned with the paralyzed side down and well protected with padding. Elevate the head approximately 6 inches (15 cm).

© American Academy of Orthopaedic Surgeons.

After you begin transport, you should relay the information you have obtained to the receiving hospital, including the time that the patient was last seen to be normal, the findings of your neurologic examination, and the time you anticipate arriving at the hospital.

Special Populations

When you are working with geriatric patients, take their past medical history into account. Patients with a history of dementia could be complicated to manage. The primary question is: "How much change has occurred in the patient's LOC?" Do not assume that the patient's baseline LOC is what you would consider "normal"; speak to the family, friends, or other caregivers to determine the patient's baseline LOC and document that level clearly. It is also important to remember that stroke is common in this age group.

Special Populations

Meningitis is a consideration when dealing with pediatric patients exhibiting signs of increased ICP. A patient with bacterial meningitis can progress rapidly from appearing mildly ill to coma and even death.

The symptoms of meningitis vary depending on the age of the child and the infectious agent. In general, the younger the child, the vaguer the symptoms. A newborn with early bacterial meningitis may have a fever as the only symptom. Young infants will often have fever and perhaps localized signs such as lethargy, irritability, poor feeding, and a bulging fontanelle. They rarely show typical signs such as nuchal rigidity until they are older. Verbal children will often complain of headaches and neck pain. An altered LOC and seizures are ominous symptoms at any age.

Children with meningococcal sepsis and meningitis get sick extremely fast, so move quickly through your assessment. Form a general impression and perform a primary survey as usual, keeping in mind that symptoms may be quite varied. Look for fever, altered mental status, bulging fontanelle, photophobia, nuchal rigidity, irritability, petechiae (small, pinpoint red spots), purpura (larger purple or black spots), and signs of shock. Assess glucose levels because hypoglycemia may result from the hypermetabolic state. Treat symptomatically and provide prompt transport to the closest, most appropriate facility.

History Taking

Obtain a history from patients who are in stable condition and have minor complaints.

If the patient is unresponsive, you will need to gather any history of the present illness from family or bystanders (**FIGURE 19-16**). If no one is around, quickly look for explanations for the altered mental status (for example, signs of trauma, medical alert tags, track marks, and environmental clues such as empty alcohol or medication containers).

Question the responsive patient about the chief complaint. If the mental status is altered, look for signs and symptoms that may indicate a cause, such as a stroke (eg, hemiparalysis or single-side weakness), and determine whether there is any evidence of a seizure (eg, incontinence or a bitten tongue). Evaluate the patient's speech. Is the patient making any sense? Is speech slurred?

Look for any obvious trauma or explanations if you suspect the patient may have had a seizure.

If the patient has a headache, try to determine the patient's level of stress, possible infections, and history of headaches. Stroke patients can also experience headaches. If you suspect a more complicated problem, perform a rapid scan to ensure that you give the patient the best possible care.

Obtain a SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) from the patient or bystanders if possible. Also try to speak with family or friends who may be

FIGURE 19-16 Try to speak with family members or bystanders who may have seen what happened. They may also be able to tell you when the patient last appeared "normal."

© Jones & Bartlett Learning.

able to explain the events leading up to the altered mental status, remembering that time can be critical in a neurologic emergency. Many times, you will find out only that the patient seemed normal when they went to sleep the night before. In such an instance, the time the patient was last seen to be normal was at bedtime, not when the patient awoke with symptoms. In some cases, pinning down the exact time the stroke began can be difficult, such as with patients who live alone.

Obtain or list all medications the patient has taken, and record the patient's general health before this episode. When possible, determine allergies and the patient's last oral intake.

Although a patient who has experienced a stroke may appear to be unresponsive and unable to speak, the patient may still be able to hear and understand what is taking place. Therefore, you should treat the patient as though their hearing is intact. Try to communicate with the patient by looking for indications that the patient can understand you, such as a glance, gaze, motion or pressure of the hand, effort to speak, or head nod. Allow the patient to write responses if they are able. Reassure the patient often. Establishing effective communication can help you to calm the patient and lessen the fear that accompanies an inability to communicate.

For patients who have had a seizure, your SAMPLE history should reveal whether the patient has a history of seizures. If so, it is important to find out how the patient's seizures typically occur and whether this episode differs in some way from previous episodes. You should also ask what medications the patient has been taking and confirm medication compliance. A patient who takes phenytoin (Dilantin) and phenobarbital (for example, Solfoton) most likely has a seizure disorder. You might find that the patient ran out of medication or stopped taking the medication for a time. Patients who have a history of seizures *and* diabetes may use up all the glucose in the body to fuel the seizure resulting in hypoglycemia and an altered mental status that does not resolve spontaneously after the patient's seizure stops.

If the patient does not have a history of seizures and now suddenly has a seizure, a serious condition, such as a brain tumor, intracranial bleeding, or serious infection, should be suspected. You should also determine whether the patient takes medications

that lower the blood glucose level, such as insulin and oral hypoglycemic agents. In other situations, you may want to inquire about drug use or exposure to poisons.

Secondary Assessment

As soon as possible, perform a secondary assessment. Look for potential causes of neurologic signs and symptoms, such as trauma not previously noticed. Does the patient have any complaints related to the abdomen? Signs of nausea and vomiting are common with some neurologic conditions, such as headaches and increased ICP. Note whether the patient is incontinent; urinary and fecal incontinence are common findings with seizures or syncope. The patient should also be assessed for injuries, including head lacerations, shoulder dislocation, bitten tongue, and long bone fractures.

Rapid identification of a stroke is imperative. You should perform at least three key physical tests on patients you suspect of having experienced a stroke: tests of speech, facial movement, and arm movement. If any one of the three is positive (abnormal), you should assume that the patient is experiencing (or has had) a stroke.

Words of Wisdom

In the hospital, the most commonly used instrument for evaluating a possible stroke is the National Institutes of Health (NIH) Stroke Scale. This 11-step numeric grading system provides the hospital with very specific information about the patient's condition. In addition, the NIH evaluation can be repeated throughout the patient's hospital stay to compare numeric values related to their changes in condition. This scale is rarely used in the prehospital setting due to its complexity; however, some components of this evaluation can be assessed by asking the patient to identify common objects in the room and to read a short written passage.

Common stroke assessment tools include the Cincinnati Prehospital Stroke Scale (**TABLE 19-4**) and the Los Angeles Prehospital Stroke Screen (**TABLE 19-5**). Also, the checklist presented in **TABLE 19-6** will help you focus on gathering the information that the emergency department physician will need before administration of fibrinolytic medications can be considered.

TABLE 19-4 Cincinnati Prehospital Stroke Scale

Assessment	Normal	Abnormal
Facial Droop		
Ask the patient to smile and show their teeth.	Both sides of face move equally well.	One side of face does not move as well as the other side.
Arm Drift		
Ask the patient to close their eyes and hold both arms out with palms up for 10 seconds.	Both arms move the same or neither arm moves. (If neither arm moves, then this may indicate the patient did not understand the instructions. Perform the test again.)	One arm does not move, or one arm drifts down compared with the other.
Speech		
Ask the patient to say, "The sky is blue in Cincinnati."	Patient uses correct words with no slurring.	Patient slurs words, uses inappropriate words, or is unable to speak.

Interpretation: If any one item is abnormal, then the probability of a stroke is 72%.

© Jones & Bartlett Learning.

TABLE 19-5 Los Angeles Prehospital Stroke Screen

Criteria	Yes	Unknown	No
1. Age >45 years	☐	☐	☐
2. History of seizures or epilepsy absent	☐	☐	☐
3. Symptoms <24 hours	☐	☐	☐
4. At baseline, patient does not use a wheelchair or is not bedridden.	☐	☐	☐
5. Blood glucose between 60 and 400 mg/dL	☐	☐	☐
6. Obvious asymmetry (right vs left) in any of the following three exam categories (must be unilateral):	☐	☐	☐
	Equal	Right Weak	Left Weak
Facial smile/grimace	☐	☐ Droop	☐ Droop
Grip	☐	☐ Weak grip ☐ No grip	☐ Weak grip ☐ No grip
Arm strength	☐	☐ Drifts down ☐ Falls rapidly	☐ Drifts down ☐ Falls rapidly

Interpretation: If criteria 1–6 are marked yes, the probability of a stroke is 97%.

TABLE 19-6 Sample Prehospital Fibrinolytic Checklist for Stroke

Use this checklist for all patients suspected of experiencing a stroke.

DATE: _____ TIME: _____	Time signs and symptoms began (record time). If unknown, answer the next question.	
DATE: _____ TIME: _____	Time patient was last seen to be normal (record time)	
_____ mg/dL	Blood glucose level (record number)	
_____/_____ Manual Automatic Right arm Left arm	Blood pressure (record readings, circle method and location)	
Yes	No	(Check Yes or No for each item.)
☐	☐	Facial droop?
☐	☐	Slurred speech?
☐	☐	Arm drift (eyes closed and held for 10 seconds)?
☐	☐	In the past 7 days, has the patient undergone a procedure in which an artery was punctured?
☐	☐	In the past 14 days, has the patient undergone a major operation or serious trauma?
☐	☐	In the past 21 days, has the patient had any bleeding from the gastrointestinal or urinary tract?
☐	☐	In the past 3 months, has the patient experienced a myocardial infarction, stroke, or head trauma?
☐	☐	When the signs and symptoms began, did the patient experience a seizure?
☐	☐	Are current bleeding or clotting problems evident?
☐	☐	Is the patient taking anticoagulant medication?
☐	☐	Does the patient have intracranial bleeding either now or in the past?
☐	☐	Are the patient's signs and symptoms of stroke rapidly improving?

© Jones & Bartlett Learning.

All patients with altered mental status (stroke, TIA, seizure of unknown cause) should also have a GCS score calculated (**TABLE 19-7**).

Given how critical normal perfusion of the brain is, blood pressure must be closely monitored in any patient with a potential ICP problem. Frequent assessment becomes even more essential when a decrease in blood pressure is also present. For any patient at risk for increased ICP, ensure a systolic blood pressure of at least 110 to 120 mm Hg is maintained.

Changes in pupil size and reactivity may indicate herniation typically associated with substantial bleeding and/or pressure on the brain. As pressure is increased, the pupil on the injured side of the brain will become larger or fully dilated (blown) as the oculomotor nerve is compressed by the swelling. If the patient has an altered mental status (regardless of the cause), you should check the blood glucose level. During most active seizures, it is impossible to evaluate vital signs. Unless the situation is unusual, vital signs in a postictal state will approximate

TABLE 19-7 Glasgow Coma Scale

Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to sound	3	Confused conversation	4	Localizes to pressure	5
In response to pressure	2	Words	3	Withdraws from pressure	4
No response	1	Sounds	2	Abnormal flexion	3
		None	1	Extension	2
				No response	1

^aSome systems use a “Not testable (NT)” score for any element that cannot be tested. Eye opening cannot be tested in a patient whose eyes are closed due to a local factor, such as swelling; verbal response cannot be tested in a patient who has a preexisting factor interfering with communication, such as mutism; and motor response cannot be tested in a patient who has preexisting paralysis or other limiting factor.

Score: 13–15 may indicate mild dysfunction, although 15 is the score a person without neurologic impairment would receive.

Score: 9–12 may indicate moderate dysfunction.

Score: 8 or less is indicative of severe dysfunction.

© Jones & Bartlett Learning.

Words of Wisdom

Stroke scales evaluate balance, eyes, the face, arms, speech, and time of onset, which can be remembered with the mnemonic BE-FAST (**TABLE 19-8**). If the patient does not have a normal response to these evaluations, you should strongly suspect a stroke. Rapid transport to a designated stroke center is indicated.

In addition, a newer scoring system called the 3-Item Stroke Severity Scale, sometimes called the

LAG scale, looks specifically at three items—**l**evel of consciousness, **a**rm drift (motor function), and **g**aze. This system may be used to assess the likelihood your patient is experiencing a stroke. Each item is scored from 0 to 2, with zero (0) being normal and two (2) being a severe abnormality (**TABLE 19-9**). Data show that a score of 5 or 6 indicates a high probability the patient is experiencing a stroke.

TABLE 19-8 BE-FAST Stroke Assessment

Balance	Did the patient experience a sudden loss of balance or inability to walk?
Eyes	Is there a change in vision? Loss of vision, double vision, or no side or top vision?
Facial droop (Ask patient to show teeth or smile.)	Does one side of the patient's face droop when smiling?
Arm drift (Ask patient to close eyes and hold both arms out with palms up.)	Does the patient demonstrate weakness or the inability to move one of the arms?
Speech	Is the patient slurring words or using words that do not make sense?
Time	When did the symptoms first appear? Do not delay transport to an appropriate stroke facility.

© Jones & Bartlett Learning.

TABLE 19-9 3-Item Stroke Severity Scale (LAG)

Item	Criteria	Score
Level of consciousness	Normal	0
	Mild dysfunction	1
	Severe dysfunction (unconscious)	2
Arm drift (hemiparesis)	Normal function	0
	Mild dysfunction	1
	Severe dysfunction (flaccid)	2
Gaze	Normal gaze (follows pen/finger to left and right sides)	0
	Mild dysfunction	1
	Severe dysfunction (fixed gaze)	2
Score (total)		>4 indicates stroke is likely

© Jones & Bartlett Learning.

Become familiar with what is used in your local protocol.

Recently, it has been determined that large vessel occlusion (LVO) strokes, which are a subtype of ischemic stroke, can be fairly reliably identified by EMS. These strokes, caused by an occlusion of a large blood vessel in the brain, respond well to fibrinolytics or mechanical thrombectomy but require rapid identification to provide the best results. The Los Angeles Motor Scale (LAMS), which is based on the

Los Angeles Prehospital Stroke Screen, was developed to identify LVO strokes faster and more accurately to guide EMS to the best transport destination for the patient. The LAMS gives points for facial droop (absent = 0, present = 1), arm drift (absent = 0, slow drift = 1, rapid fall = 2), and grip strength (normal = 0, weak grip = 1, no grip = 2). A score of 4 or more is a strong indication of an LVO stroke and indicates consideration of transport to a comprehensive stroke center, if available.

normal. Obtain pulse rate, rhythm, and character; respiratory rate, quality, and degree of distress; blood pressure; skin color, temperature, and condition; blood glucose level; and pupil size and reactivity.

Glucose levels of less than 10 mg/dL are incompatible with brain functioning and typically

lethal. Chapter 10, *Patient Assessment*, discusses the use of a glucometer in detail.

Determine the pulse oximeter reading, remembering that normal readings are greater than 94% and that this number is affected by the amount of hemoglobin within the body, perfusion status, cold

Assessment Pearls

- Assess glucose levels in any patient with an altered mental status.
- Time is brain! Provide rapid assessment, treatment, and transport for suspected strokes.
- Never give IV glucose prophylactically to a patient with a possible stroke or head injury. Administer IV glucose to these patients only when levels can be assessed.
- Monitor ETCO_2 , especially with potential stroke patients.
- Monitor the airway closely in patients who are actively seizing or postictal. Suction and ventilate as needed.
- Reassess glucose levels in seizure patients. Generalized motor activity can use up glucose stores, resulting in hypoglycemia.
- Transport patients who have experienced a TIA even if the symptoms have resolved. Although the patient may have experienced a TIA before, a TIA (especially when increasing in frequency) is a sign that a stroke may be imminent.
- Maintain a blood pressure of 110 to 120 mm Hg in patients at risk of increased ICP to ensure adequate cerebral perfusion.

environments, and the presence of carbon monoxide. If possible, monitor ETCO_2 levels. Normal readings are 35 to 45 mm Hg. Higher levels suggest inadequate ventilation and lower levels suggest hyperventilation.

Reassessment

Reassessment is intended to reassess ABCDEs (Airway, Breathing, Circulation, Disability, and Exposure), vital signs, and interventions and to monitor patients for changes. Casual conversation will allow you to closely monitor brain functions. If the patient is nonverbal, closely observe respiratory patterns and eye and body movements, and monitor for seizure activity.

Routine monitoring should include heart rate, blood pressure, respiratory rate and pattern, pulse oximetry and/or ETCO_2 , repeated glucose level (if the level was low and glucose was given to the patient), and GCS scores. Provide oxygenation and ventilation as needed. Monitor the IV fluids closely to ensure that accidental fluid overload does not occur. Modify treatment based on patient changes.

Observe for recurrent seizures. If another seizure occurs, note whether it starts at a focal part of the body (for example, one arm or one leg) and then progresses to the rest of the body. Most important, evaluate the patient's mental status and monitor it frequently to verify progressive improvement.

Always provide emotional support. Many patients who experience seizures are frustrated with their condition and may refuse transport. Kindness and professional behavior are required to help convince a reluctant patient that transport is necessary for definitive care.

Notify the receiving facility of your patient's chief complaint and your assessment findings. Most designated stroke centers will want you to call a stroke alert for patients you have assessed and found to be experiencing a stroke (check local protocol). This will alert the stroke team members at the hospital and give them time to assemble their resources to treat the patient without delay. Be sure to communicate the time that the patient was last seen to be healthy, the findings of your neurologic examination, and estimated time of arrival.

Document your findings from your stroke scale and the score results of the GCS, along with any changes you found in your reassessment.

Document all interventions, including the position in which the patient was placed.

For patients who have experienced a seizure, give a description of the seizure activity, if known. Include bystanders' comments if they witnessed the seizure. Document the onset and duration of the seizure, and whether the patient noticed an aura. Record any evidence of trauma and interventions performed. Document whether the patient has a history of seizures and, if so, the frequency of the seizures and whether there is a history of status epilepticus. Record interventions performed and the patient's response along with the findings of continued reassessments.

Documentation and Communication

You may be the only provider to witness some patient activity, so accurate and complete documentation is critical to ensure continuity of care.

Emergency Medical Care

A patient with stroke, seizure, hypoglycemia, or hypoxia typically shows identifiable signs or symptoms, and treatment options are readily available. With other neurologic emergencies, the cause of the patient's symptoms will not always be obvious and more diagnostic testing may be needed to determine the cause. Most of your interventions will be based on your assessment findings. Your best treatment is determined by performing a thorough assessment and maintaining the ABCs.

Two medications are available for prehospital treatment of hypoglycemia: dextrose and glucagon. In patients suspected of experiencing a stroke, and *only* if the patient's blood glucose level is low, give dextrose. Consider the administration of glucagon for hypoglycemia as an alternative. Use an isotonic crystalloid solution at a to-keep-open (TKO) rate unless the patient is hypovolemic. If hypotensive, give a fluid bolus of 20 mL/kg to maintain adequate perfusion (for example, to maintain the radial pulses), reducing the flow to a TKO rate after radial pulses have returned. Excessive fluids will increase bleeding in patients with hemorrhagic strokes as well as increase ICP.

If you cannot check the patient's blood glucose level because of equipment failure, you need to be

more cautious in administering dextrose. In a situation in which the patient is unresponsive or has a decreased LOC and no blood glucose monitor is available, administer 12.5 g (one-half of a syringe) and then reassess the response. Proceed with additional dextrose cautiously, based on responses to previous doses. Hyperglycemia can increase the morbidity rate among stroke patients. Remember, however, that hypoglycemia is *more lethal* than hyperglycemia. If in doubt, err on the side of administering glucose.

When administering intravenous dextrose in the form of D₅₀ (50% dextrose in water), you must establish IV access with a large-bore catheter (preferably 18 gauge) within a large vessel because D₅₀ is quite viscous. Ensure that the IV line is patent before you attempt to give the D₅₀. Extravasation of D₅₀ into the interstitial space can cause severe damage to muscles, nerves, and skin or even death of these tissues. The usual dose is 25 g of D₅₀ or one full syringe. The effects from dextrose typically begin in 30 seconds to 2 minutes. If no effect is apparent or the patient's blood glucose level remains low, ensure adequate IV access and administer additional dextrose.

Words of Wisdom

Many jurisdictions and agencies do not use D₅₀ because of the risk to local tissues associated with the high viscosity and the need for a relatively large-gauge catheter to facilitate administration. Hypoglycemia can be treated as effectively and with fewer risks using the same total dose of glucose in a lower concentration (D₂₅ or D₁₀ [25% and 10% dextrose in water, respectively]). Although administration of the same dose of glucose requires more fluid, the solution is less viscous, less toxic to local tissues, and generally more comfortable to the patient.

Dextrose is commonly supplied in these formats. Note that these all contain the same total dose of dextrose, but the volume of fluid that must be administered increases as the concentration decreases.

- D₅₀: 25 g in 50 mL
- D₂₅: 25 g in 100 mL
- D₁₀: 25 g in 250 mL

If you cannot obtain vascular access, administer 0.5 to 1 mg of glucagon subcutaneously or intramuscularly or consider intraosseous access

for glucose administration. The LOC and blood glucose level should increase within 20 minutes after administration of glucagon. If the blood glucose level remains low, repeat the glucagon for a maximum of three doses.

Oral glucose administration is another option for patients with a decreased LOC who can protect their own airways (generally determined by their ability to speak clearly) and therefore swallow safely. Assess the patients carefully, confirming that they are awake enough to follow commands. First give them a small amount of water to drink—maybe 10 mL. If they can swallow that amount, consider administering oral glucose, 25 g (one tube). Alternatives to oral glucose include cake icing, a plain chocolate bar, or orange juice with sugar added. Administration of sugar by mouth will take longer to raise the blood glucose level. Constantly supervise patients as they consume the sugar. To the extent possible, make sure they do not aspirate.

Currently, there is no safe way to lower a high blood glucose level in the field. For patients with hyperglycemia, provide standard care and ensure adequate blood pressure. Hyperglycemic patients are often dehydrated and usually need volume support. Note that rehydration alone in a severely dehydrated patient with hyperglycemia can dramatically lower the patient's blood glucose level.

Finally, provide emotional support for the patient and family. Neurologic emergencies can produce confusion, fear, anger, and helplessness. Consider a therapeutic gentle touch on the shoulder. Touch can communicate compassion. Use a calm, reassuring voice to show that you are there to help. Try to reorient the patient often because confusion is often present in neurologic emergencies.

Stroke

Because it is often impossible to differentiate the symptoms of a TIA from a stroke, assume that a patient with TIA or stroke symptoms is experiencing a stroke. Administer supplemental oxygen to maintain SpO₂ at greater than 94% or, if needed, assist ventilations.¹¹ Establish IV access, and obtain blood samples for analysis. Transport the patient to the closest appropriate facility for evaluation.

In most patients with a suspected stroke, CT is needed for a physician to determine whether there is bleeding in the brain. If there is no bleeding, the

Special Populations

The brain gradually deteriorates and shrinks as a part of the normal aging process. These processes increase the risk of brain injury from minor forces because the brain can more readily impact the inside of the skull as a result of the increased space and because the veins that connect the brain to the dura are stretched. A reduced brain mass may also reduce the patient's mental status and capacity. A smaller brain can impair memory function. A geriatric patient with lapses in short-term memory may often ask the same or similar questions repeatedly.

When you are called to care for a geriatric patient with altered mental status, consider the possibility of a stroke or TIA. At the scene of a motor vehicle crash involving an older driver, consider a stroke or TIA as a possible cause in the crash. Be alert for altered mental status and unusual pupil responses (eg, constricted pupils in dim light, unequal pupils).

Take special note of complaints of a headache. Although geriatric patients get tension headaches, they are far less common in the older population. Consider any headache as potentially serious.

As with the general population, older people can experience seizures. Remember, seizures are not necessarily caused by epilepsy. Consider and assess for the possibility of a drug overdose, stroke, head injury, or CNS infection. Status epilepticus in a geriatric patient increases the risk of hypoxia, irregular heart rhythm, hypotension, elevated body temperature, low blood glucose level, and, if the patient vomits, aspiration.

Remember, geriatric patients are at a higher risk for CNS illnesses and injuries, including brain injury, TIA, stroke, and seizures. Do not be surprised to find a serious head injury from what you might consider a simple bump on the head.

patient may be a candidate for clot-dissolving medication that may help brain cells survive.

Most treatments for stroke must be started as soon as possible after the onset of the event (**TABLE 19-10**). Current treatments are often effective if they are started within 3 hours after the stroke begins. However, for certain patients, treatment may be effective if started up to 4.5 hours after onset.^{12,13} Therefore, even if 3 hours have passed since the onset of symptoms, prompt action on your part is essential.

In patients who are unresponsive and demonstrate other signs of increased ICP, administer fluids

TABLE 19-10 Tips on Patient Care for a Possible Stroke Patient

Patients who experience a TIA typically have the same signs and symptoms as patients who experience a stroke. These signs and symptoms can last from minutes up to 24 hours. Therefore, the signs of stroke that you note on arrival may gradually resolve. Patients who appear to have had a TIA should be transported for further evaluation.

Place the patient's affected or paralyzed extremity in a secure, safe position during patient movement and transport. Consider elevating the head 30° (6 inches [15 cm]) to assist with intracranial pressure if there is no concern for spinal injury.

Some patients who have experienced a stroke may be unable to communicate, but they can often understand what is being said around them. Be aware of this possibility.

New therapies for stroke must be used shortly after the onset of symptoms. Minimize time on the scene, and notify the receiving hospital as soon as possible.

Abbreviation: TIA, transient ischemic attack

© Jones & Bartlett Learning.

as needed. Unless you are concerned about possible spinal injury, elevate the patient's head 30°. ⁵ This change will cause a slight decrease in ICP. Ensure that the airway is clear, but do not vigorously suction because stimulating the cough and gag reflexes will increase ICP. Watch for seizures and call early for paramedic backup. The patient may also be bradycardic because of the increased ICP. Notify the hospital and provide rapid transport.

It is important for you to monitor blood pressure closely in any patient with a potential problem with ICP. Frequent assessment becomes even more critical when a decrease in blood pressure is also present. For any patient at risk for ICP problems, ensure that the systolic blood pressure remains at least 110 to 120 mm Hg.

Carbon dioxide and oxygen levels are important in patients with increased ICP. A low carbon dioxide level causes constriction of the cerebral arteries. This vasoconstriction further impairs perfusion to the brain. Low oxygen levels markedly increase mortality in patients with brain injury. Never allow a patient with brain injury or stroke to become hypoxic. Restoration of normal levels of ventilation

is critically important. In general, do not hyperventilate patients, as doing so may decrease CPP.

In select situations associated with evidence of markedly increased ICP and impending herniation, a slight increase in the ventilatory rate to approximately 20 breaths/min with a goal of decreasing the ETCO_2 levels to 30 to 35 mm Hg may be valuable.^{5,14} These circumstances include patients with an acute deterioration in their GCS score by 2 or more points and a resultant GCS that is less than 9. In addition, patients with a GCS score less than 9 in whom a unilateral pupillary dilation develops that is unresponsive to light (blown pupil) are at risk for acute herniation and might benefit from limited hyperventilation.

The AHA Adult Suspected Stroke Algorithm is shown in its entirety in **FIGURE 19-17**. Note that many of the steps, particularly those in the initial boxes, are intended for prehospital providers. Treatment at the hospital takes different paths of care for each type of stroke. One feature, however, is common to both: time is essential. For ischemic strokes, fibrinolytics need to be administered within 3 to 4.5 hours of onset. In hemorrhagic strokes, the more the patient bleeds into the cranium, the greater the potential for increased ICP and brainstem damage.

Regarding hypertension, currently, there is no AHA/American Stroke Association guideline for its control in the prehospital setting. Do not administer

aspirin in the field; it is helpful in patients with ischemic stroke but is harmful in patients with hemorrhagic stroke. Aspirin should be administered only after CT or magnetic resonance imaging has been completed in the hospital.

Finally, because patients may not be able to feel or move their arms or legs, make sure to protect them from injury.

Transient Ischemic Attack

As with strokes, management of TIAs begins with standard care. Follow the same management guidelines as for stroke. Close neurologic assessment is needed. Patients may experience multiple TIAs in a short time frame.

Strongly encourage the patient to be transported. If the patient refuses transportation, appeal to the patient's family for assistance. Encourage the patient to seek medical care very soon. Offer to return, and tell the patient to call 9-1-1 again if the situation changes. It is important to reinforce the message that the TIA is a warning sign of a serious and potentially deadly problem with the blood vessels in the brain.

Seizures

In most situations, patients who have had a seizure require definitive evaluation and treatment in the

YOU are the Provider

Part 4

As you are transporting the patient, you perform a rapid full-body scan to rule out the possibility of trauma as a cause of his symptoms. Finding no trauma and having ruled out the possible conditions mimicking stroke, you are confident in your initial suspicion that this patient has experienced a stroke. You attempt to ask the patient about onset, symptoms, and other pertinent findings. However, you are unable to obtain useful information because of the patient's slurred speech.

Recording Time: 23 Minutes

Respirations	12 breaths/min
Pulse	Strong and regular; 71 beats/min
Skin	Warm and dry
Blood pressure	266/174 mm Hg
Oxygen saturation (SpO_2)	100% at 15 L/min via nonrebreathing mask
Pupils	Left pupil nonreactive

7. What is the most important piece of information to give to the receiving physician regarding this patient's stroke?

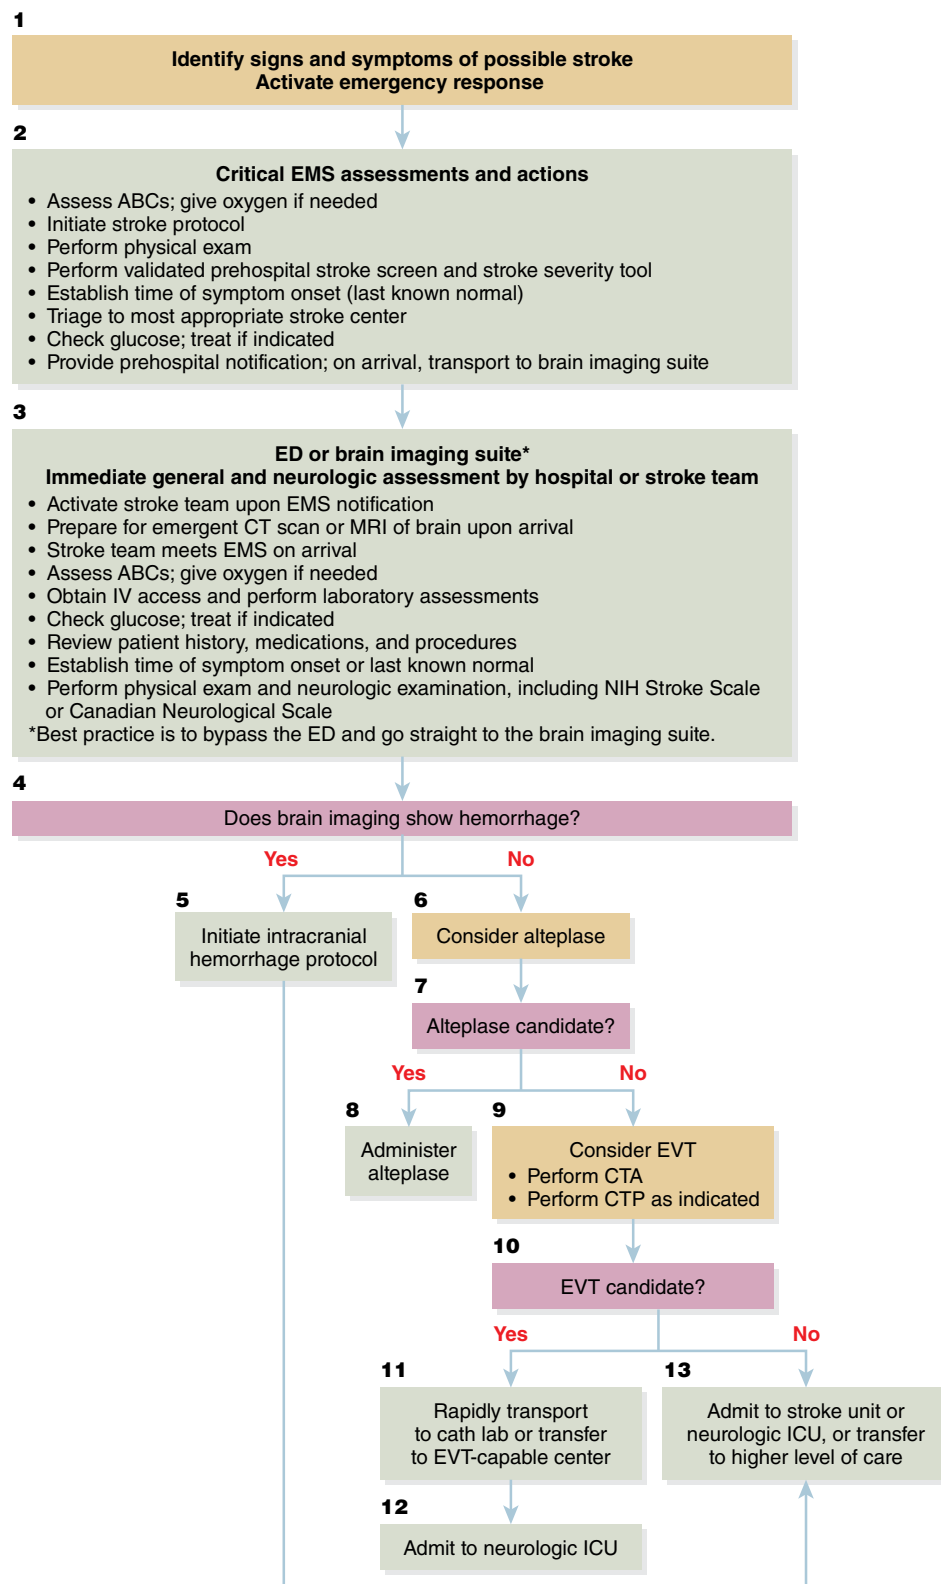

FIGURE 19-17 The Adult Suspected Stroke Algorithm from the American Heart Association. The steps in the initial boxes are intended for prehospital providers.

Abbreviations: ABC, airway, breathing, and circulation; CT, computed tomography; CTA, CT angiography; CTP, CT perfusion; ED, emergency department; EVT, endovascular thrombectomy; ICU, intensive care unit; IV, intravenous; MRI, magnetic resonance imaging; NIH, National Institutes of Health

hospital. Even a patient who has a history of chronic epilepsy that is controlled with medications may have an occasional seizure, commonly referred to as a breakthrough seizure, and should also be taken to the hospital for evaluation. At the hospital, blood levels of seizure medications are checked to ensure that patients are receiving the correct dose. Clearly, patients who have just had their first seizure and patients with chronic seizures who have had an episode that is “different” require immediate evaluation to rule out life-threatening conditions.

For patients who are having a seizure, protect them from harm, maintain a clear airway by suctioning as necessary, and provide oxygen as quickly as possible. If trauma is suspected, provide spinal immobilization. With recurrent seizures, protect the patient from further injury, and manage the airway after the seizure ceases.

For patients who continue to have a seizure, as in status epilepticus, suction the airway, provide positive-pressure ventilations (bag-mask ventilations), and transport quickly to the hospital. If you have the option to rendezvous with paramedics, you should do so. Paramedics can administer medications that can stop a prolonged seizure.

Administer oxygen as necessary to maintain an SpO_2 greater than 94% to any patient who has experienced a seizure, whether it is the first or whether the patient has chronic seizures. This intervention will help improve any associated hypoxia. Gain IV access as a medication route even if fluid resuscitation is not needed. Note any medications the patient is currently taking and any previous seizures, the time of onset, the duration of the seizure activity, the number of seizures, and whether the patient was responsive between seizures. Provide spinal immobilization if trauma was involved or cannot be ruled out.

Depending on local protocols, you should assess and treat the patient for possible hypoglycemia (for example, a person with diabetes who has altered mental status and takes insulin or oral agents that lower the blood glucose level). Look for tongue lacerations and bleeding that may create an obstruction or lead to aspiration. With recurrent seizures, protect the patient from further injury and manage the airway as needed.

If you are treating a child whom you suspect is having a febrile seizure, you should attempt to lower the body temperature by removing the child's

clothing and cooling the child with tepid water, particularly around the head and neck, and then fanning the moistened areas. Be careful not to make the patient shiver, which will further increase temperature and precipitate another seizure.

In all cases, you should exhibit patience and tolerance because many of the patients are likely to be confused and, occasionally, frightened. Many patients who experience seizures are frustrated with their condition and may refuse transport. Compassion and professional behavior are required to help convince the patient that transport is necessary for definitive care.

Special Populations

Children can have altered mental status caused by strokes, seizures, and other brain emergencies. However, children who have subarachnoid hemorrhages may not have a berry aneurysm; instead, they may have a congenital problem with the blood vessels in the brain known as an arteriovenous malformation. Children who have sickle cell anemia are at particularly high risk for ischemic stroke. Treat stroke in children the same way that you do in adults.

As mentioned, seizures can result from sudden high fever, particularly in children. Remember that although febrile seizures are generally well tolerated by children, you must transport them to the hospital. The possibility of a second seizure makes transport mandatory so that if other problems develop, the child is in the hospital and can receive immediate, definitive care.

Always assess glucose levels in any patient with an altered mental status. The alteration may be entirely a result of hypoglycemia, or there may be another cause. Either way, hypoglycemia is easy to rule out and can be corrected if present. Also, patients with hypoglycemia require close monitoring, particularly of the airway, en route to the hospital.

Syncope

Begin with standard care. Determine whether the patient may have experienced trauma because of the fall, and take cervical spine precautions as needed. Focus on the blood glucose level and likely cardiac causes. Obtain orthostatic vital signs, if possible. Provide supplemental oxygen and gain IV access. If the patient's blood pressure remains low, then provide fluids as appropriate, based on the cause of the hypotension. It is important to

transport any patient who has a syncopal episode to the hospital to determine the cause.

Provide emotional support; a syncopal episode can be embarrassing. Syncope can be a sign of life-threatening cardiac dysrhythmias, stroke, and other serious medical conditions. Call early for paramedic backup if needed.

Headache

Be cautious because headaches can indicate a more serious problem. Give standard care. Ask which medications the patient has taken. Many patients will appreciate a darkened, quiet environment, so do not use lights and siren if transporting.

YOU are the Provider SUMMARY

1. What mnemonic is useful for assessing adult patients with altered mental status?

When assessing adult patients with altered mental status, consider the mnemonic AEIOU-TIPS. This mnemonic will assist in ruling in or out possible causes of altered mental status.

2. What are the two types of abnormal posturing, and what do they indicate?

There are two main abnormal postures that the patient may demonstrate with painful stimulation: decorticate and decerebrate. If you see either posture, you should immediately consider the patient to be in critical condition, because these postures represent substantial impairment in brain function. In decorticate posturing, patients demonstrate abnormal flexion by flexing the arms and curling them toward the chest, pointing the toes, and flexing the wrists. You can easily remember the meaning of decorticate posturing because the patient's hands are flexed toward the core. In decerebrate posturing (also known as extension posturing), patients again point the toes, but now extend the arms outward and rotate the lower arms in a palms-down manner (called pronation). The wrists are again flexed. This posture is a more severe finding than decorticate posturing.

3. What are the two types of strokes that this patient may be experiencing?

There are two main types of stroke: hemorrhagic and ischemic. An ischemic stroke is caused when blood flow to a particular part of the brain is cut off by a blockage (clot) inside a blood vessel. This can be from a thrombosis or an embolism that blocks blood flow. A hemorrhagic stroke occurs as a result of bleeding inside the brain, typically when a cerebral artery ruptures. The severity of the hemorrhagic stroke depends on the location and size of the ruptured cerebral vessel. As bleeding continues within the brain, ICP increases and compresses brain tissue. When brain tissue is compressed, oxygenated blood cannot get into the area, and the surrounding cells begin to die.

4. Should you move the patient into the back of the ambulance for evaluation?

Further assessments should be deferred until the patient is in the back of the ambulance. If you believe that the patient is experiencing a stroke, "time is brain," and the sooner you are able to transfer the patient to definitive care, the better the patient outcome will be. You should also have a suction unit ready as these patients are likely to vomit.

5. What conditions mimicking stroke should AEMTs consider?

The following three conditions may present similarly to stroke:

- Hypoglycemia (a condition characterized by a low blood glucose level)
- A postictal state (a period following a seizure that lasts between 5 and 30 minutes, characterized by labored respirations and some degree of altered mental status)
- Subdural or epidural bleeding (a collection of blood near the skull that presses on the brain)

Because oxygen and glucose are needed for brain metabolism, a patient with hypoglycemia may present like a patient who is experiencing a stroke. Find out whether the patient's medical history includes diabetes.

A patient in the postictal state may appear to be experiencing a stroke. However, in most cases, a patient having a seizure will recover rapidly (within several minutes), whereas a patient experiencing a stroke will not.

Subdural and epidural bleeding usually occur as a result of trauma. With subdural and epidural bleeding, the onset of strokelike signs and symptoms may be subtle. The patient or family may not even remember the original injury that is causing the bleeding.

6. Should this patient receive a bolus of IV fluid?

A bolus of IV fluid for this patient is absolutely contraindicated because of his current hypertension. By administering fluid, you could potentially increase

YOU are the Provider **SUMMARY** *continued*

the patient's blood pressure, which could increase the patient's ICP, causing his condition to worsen.

7. What is the most important piece of information to give to the receiving physician regarding this patient's stroke?

The most important piece of information you can give the receiving physician is the onset of symptoms, or the time the patient was last seen as normal. This information will help physicians in the emergency department decide whether it is safe

to begin certain treatments (such as thrombolytic therapy) that must be given within a narrow time frame after the onset of symptoms. You may be the only person with the opportunity to speak with bystanders to obtain this critical information. Many times, you will be able to find out only that the patient seemed normal when they went to sleep the night before. In such cases, the time the patient was last seen to be normal was at bedtime, not when the patient awoke with symptoms.

Narrative

EMS dispatched to above location for possible intoxicated patient. On arrival, met by shelter staff who direct us to patient, well known to EMS, who is found seated on floor, leaning against wall. Patient is alert but has very slurred speech and is unable to answer any questions appropriately. Right-side facial droop noted, along with possible left-side weakness. Cincinnati Prehospital Stroke Scale screening performed; patient "failed" all portions of test. Online medical control (OLMC) contacted with "stroke alert," but OLMC informed us to transport patient to MGH due to lack of neurologist services available. Center staff states patient has alcoholism, but he does not believe that he had a drink yet today. He further states that he last saw the patient as normal about 20 or 30 minutes before calling EMS. Placed patient on cot, secured × 3, initiated emergency transport to MGH. En route: Vitals as above. 18-gauge IV established in left antecubital vein, TKO. Patient is able to maintain a patent airway and handle his own secretions. Rapid scan performed; no obvious trauma noted. Blood glucose noted to be 112 mg/dL. Report called to MGH with condition and ETA. On arrival, care and report given to awaiting stroke team without incident.

End of report

Prep Kit

Ready for Review

- The nervous system is the most complex organ system within the human body and consists of the brain, spinal cord, and thousands of nerves. This system is responsible for fundamental functions, such as controlling breathing, heart rate, and blood pressure, and higher-level activities. Many disorders can cause neurologic symptoms.
- The central nervous system is responsible for thought, perception, feeling, and autonomic body functions. The peripheral nervous system transmits commands from the brain to the body and receives feedback from the body.
- The cerebrum, the largest part of the brain, is divided into right and left hemispheres, each controlling the opposite side of the body.
- A CVA or stroke is an interruption of blood flow to the brain that often is sudden and results in the loss of function in the affected part of the brain. Loss of brain function occurs within minutes, and brain cells begin to die. Signs and symptoms of stroke include receptive or expressive aphasia; dysarthria; muscle weakness or numbness on one side; facial droop; and, sometimes, hypertension.
- After cells are infarcted, they are dead and cannot be restored; however, cell death may take several hours to occur. Ischemic cells are those that are alive but do not have enough oxygen to function properly; however, function can be restored if normal blood flow is restored to that area of the brain in a timely manner.
- The two types of stroke are hemorrhagic and ischemic. Ischemic stroke occurs when blood flow to part of the brain is cut off by a blockage inside a cerebral artery. Hemorrhagic stroke occurs as a result of bleeding within the brain, typically when a cerebral artery ruptures.
- Hemorrhagic strokes place patients at risk for increased ICP. Increased pressure within the cranial vault may cause the brain to become ischemic or to herniate.
- In a TIA, normal body processes break up the blood clot, restoring blood flow and ending symptoms in less than 24 hours. However, patients with transient ischemic shock are at high risk for a full stroke.
- Because current treatments must be administered within 3 to 4.5 hours of the onset of symptoms to be most effective, you should provide prompt transport.
- Seizures are characterized by unresponsiveness and generalized twitching of all or part of the body. There are three types of seizures that you should learn to recognize: generalized, focal, and febrile.
- Seizures may be caused by a congenital disorder, a diabetic emergency, or a fever (if the patient is an infant or child).
- Most seizures last between 3 and 5 minutes and are followed by a postictal state in which the patient may be unresponsive, have labored breathing and hemiparesis, and may have been incontinent. It is important for you to recognize the signs and symptoms of seizures so that you can provide emergency department staff with information during transport.
- Altered mental status is also a common neurologic problem that you will encounter. Signs, symptoms, and causes vary widely. Common causes include hypoglycemia, alcohol intoxication, drug overdose, and poisoning.
- Patients with hypoglycemia can have signs and symptoms that mimic stroke and seizures. The principal difference is that a patient who has experienced a stroke may be alert and

attempting to communicate normally, whereas a patient with hypoglycemia almost always has an altered mental status.

- Types of headaches include tension headaches, migraines, and sinus headaches; these are not life threatening, but patients have real pain and need emergency medical services assistance.
- Look for scene clues such as overturned furniture or medical alert tags. Note the patient's position and LOC and, as always, immediately address the airway, breathing, and circulation. Do not suction vigorously. Stimulating the cough and gag reflexes will increase the ICP.
- Be alert for the Cushing reflex, a combination of three conditions: rising blood pressure, falling heart and respiratory rates, and widened pulse pressure (systolic hypertension). These findings indicate increased ICP.
- Rapidly transport patients in critical condition and patients in whom you suspect stroke. If possible, stroke patients should be taken to a facility that has the ability to administer fibrinolytic drugs.
- Always notify the hospital as soon as possible that you are bringing in a patient with a possible stroke so that staff can prepare to test and treat the patient without delay.
- When obtaining the patient's history, ask what happened; evaluate the patient's speech; find out when the patient's symptoms began; and find out if the patient has a history of stroke, TIA, seizure, or diabetic conditions.
- You should always perform at least three neurologic tests on patients you suspect of experiencing a stroke: speech, facial movement, and arm movement. You may use a stroke assessment tool such as the Cincinnati Prehospital Stroke Scale or the Los Angeles Prehospital Stroke Screen.
- All patients with altered mental status should also have a GCS score calculated.
- Interventions will be based on assessment findings and may include providing 100% oxygen, assisting ventilations, providing spinal immobilization, administering oral glucose, establishing intravenous access, obtaining blood samples, administering intravenous dextrose, administering glucagon, and administering fluid.

Vital Vocabulary

absence seizures Seizures that may be characterized by a brief lapse of attention in which the patient may stare and does not respond; formerly known as a petit mal seizure.

aphasia The inability to understand or produce speech.

arterial rupture The rupture of an artery. Involvement of a cerebral artery may contribute to interruption of cerebral blood flow.

ataxia A staggered walk or gait caused by injury to the brain or spinal cord.

atherosclerosis A disorder in which cholesterol and possibly calcium build up inside the walls of blood vessels, forming plaque, which eventually

leads to partial or complete blockage of blood flow; a plaque can become a site where blood clots can form, detach, and travel elsewhere in the circulatory system (embolize); the most common form of arteriosclerosis.

aura Sensations experienced before an attack occurs; common in seizures and migraine headaches.

axon A long, slender extension of a neuron (nerve cell) that conducts electrical impulses away from the neuronal soma.

cerebral embolism Obstruction of a cerebral artery caused by a clot that was formed elsewhere in the body and traveled to the brain.

cerebrovascular accident (CVA) Interruption of blood flow to the brain that results in the loss of brain function; also referred to as a stroke or brain attack.

clonic phase Seizure movement marked by repetitive muscle contractions and relaxations in rapid succession.

coma A state in which a person does not respond to either verbal or painful stimuli.

decerebrate posturing Posturing characterized by extension of the arms and legs, in which the arms rotate in a palms-down manner and the toes point; indicates pressure on the brainstem and may appear in patients with severe brain trauma.

decorticate posturing Posturing characterized by flexion of the arms and extension of the legs, in which the arms flex and curl toward the chest, the wrists flex, and the toes point; indicates pressure on the brainstem and may appear in patients with severe brain trauma.

dysarthria The inability to pronounce speech clearly; often due to loss of the nerves or brain cells that control the small muscles in the larynx.

dysphagia Pain, discomfort, or difficulty in swallowing.

febrile seizures Seizures that result from sudden high fever, particularly in children.

focal seizures Seizures that start in one area of the brain; classified as either aware or impaired-awareness, and further as motor or nonmotor (absence).

generalized seizures Seizures that result from abnormal electrical discharges from large areas of the brain, involving both hemispheres.

generalized tonic-clonic seizures Seizures characterized by severe twitching of all of the body's

muscles that may last several minutes or more; formerly known as a grand mal seizure.

hemiparesis Weakness on one side of the body.

hemorrhagic stroke One of the two main types of stroke; occurs as a result of bleeding inside the brain.

herniation A process in which tissue is forced out of its normal position, such as when the brain is forced from the cranial vault, either through the foramen magnum or over the tentorium.

hypoglycemia Abnormally low glucose level in the blood.

idiopathic Of no known cause.

incontinence Loss of bowel and bladder control; can be due to a generalized tonic-clonic seizure and to other conditions.

infarcted cells Cells that die as a result of loss of blood flow.

intracranial pressure (ICP) The pressure within the cranial vault; normally 0 to 15 mm Hg in adults.

ischemic cells Cells that receive enough blood after an event, such as a cerebrovascular accident, to stay alive but not enough to function properly.

ischemic stroke One of the two main types of stroke; occurs when blood flow to a particular part of the brain is cut off by a blockage (for example, a clot) inside a blood vessel.

myelin An insulating layer, or sheath, made up of fatty substances and protein that form around the nerves.

neurotransmitters The chemicals produced by the body that stimulate electrical reactions in adjacent neurons.

postictal state The period following a seizure that lasts between 5 and 30 minutes,

characterized by labored respirations and some degree of altered mental status.

pronation The act of rotating the forearms in a palms-down manner.

seizures Episodes often characterized by generalized, uncoordinated muscular activity associated with loss of consciousness; a convulsion.

status epilepticus A condition in which seizures recur every few minutes without a lucid interval or last more than 4 or 5 minutes.

stroke A loss of brain function in certain brain cells that do not get enough oxygen during a cerebrovascular accident. Usually caused by obstruction of the blood vessels in the brain that feed oxygen to the brain cells.

synapse The gap between nerve cells across which nervous stimuli are transmitted.

syncope The temporary loss of consciousness and postural tone caused by diminished cerebral blood flow.

thrombus In neurologic emergencies, the local clotting of blood in the cerebral arteries that may result in the interruption of cerebral blood flow and subsequent stroke.

tonic phase In a seizure, the steady, rigid muscle contractions with no relaxation.

transient ischemic attack (TIA) A disorder of the brain in which brain cells temporarily stop working because of insufficient oxygen, causing strokelike symptoms that resolve completely within 24 hours of onset.

trismus The involuntary contraction of the mouth resulting in clenched teeth; occurs during seizures and head injuries.

uremia The presence of excessive amounts of urea and other waste products in the blood; severe renal failure resulting in the buildup of waste products within the blood; eventually impairs brain function.

Chapter 20

Gastrointestinal and Urologic Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Abdominal and Gastrointestinal Disorders

Anatomy, presentations, and management of shock associated with abdominal emergencies

- Gastrointestinal bleeding (pp 1034–1040)

Anatomy, physiology, pathophysiology, assessment, and management of

- Acute and chronic gastrointestinal hemorrhage (pp 1040–1043)

- Peritonitis (pp 1037–1040)
- Ulcerative diseases (pp 1044–1045)

Genitourinary/Renal

- Blood pressure assessment in hemodialysis patients (pp 1057–1059)

Anatomy, physiology, pathophysiology, assessment, and management of

- Complications related to:
 - Renal dialysis (pp 1057–1059)
 - Urinary catheter management (not insertion) (p 1059)
- Kidney stones (pp 1047–1048)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the gastrointestinal and renal systems. (pp 1034–1036)
2. Define the term *acute abdomen*. (p 1037)
3. Define peritonitis and list its potential signs and symptoms. (pp 1037–1038)
4. Explain the concept of referred pain. (p 1038)
5. Recognize that abdominal pain can arise from other body systems. (pp 1038–1039)
6. Discuss the various potential causes of acute abdomen, including gastrointestinal hemorrhage (eg, from esophagitis, gastroesophageal reflux disease, peptic ulcer disease, Mallory-Weiss tear, esophageal varices, or hemorrhoids) and nonhemorrhagic conditions (eg, gallstones, pancreatitis, appendicitis, gastroenteritis, diverticulitis). (pp 1039–1044)
7. Discuss the pathophysiology of chronic inflammatory abdominal conditions, including ulcerative colitis, irritable bowel syndrome, and Crohn disease. (pp 1044–1046)
8. Discuss the various types of urologic pathophysiology, including urinary tract infections. (pp 1046–1047)
9. Discuss the various types of renal pathophysiology, including kidney stones, acute kidney injury, chronic kidney disease, and end-stage renal disease. (pp 1047–1048)

10. Identify gynecologic conditions that can cause abdominal pain, including pelvic inflammatory disease and ectopic pregnancy. (p 1048)
11. Identify male genital tract conditions that can cause abdominal pain, including epididymitis, priapism, benign prostate hypertrophy, testicular masses, and testicular torsion. (pp 1048–1049)
12. Identify pathophysiologies of other organ systems that can lead to gastrointestinal and urologic conditions, including aneurysm and hernia. (pp 1049–1050)
13. Describe the assessment process for patients with an acute abdomen or urologic emergency. (pp 1050–1051)
14. Describe the procedures to follow in managing the patient with shock associated with abdominal emergencies. (p 1052)
15. Discuss general management of a patient with an acute abdomen or urologic emergency. (pp 1056–1057)
16. Explain the purpose of renal dialysis. (pp 1057–1059)
17. Describe potential complications of dialysis or a missed dialysis treatment. (p 1059)

SKILLS OBJECTIVE

1. Demonstrate the assessment of a patient's abdomen. (pp 1050–1057)

Introduction

Abdominal pain is a common complaint among patients, but the cause is often difficult to identify, even for a physician. As an advanced emergency medical technician (AEMT), you do not need to determine the exact cause of acute abdominal pain: you simply need to be able to recognize a life-threatening problem and act swiftly in response. Remember, the patient is in pain and is probably anxious, requiring all your skills of rapid assessment and emotional support.

This chapter begins by explaining the anatomy and physiology of the gastrointestinal (GI) and genitourinary systems. It then discusses the pathophysiology of an acute abdomen, including signs and symptoms of the acute abdomen and the procedure for examining the abdomen. Finally, it discusses the different causes of an acute abdomen and appropriate emergency medical care.

Anatomy and Physiology Review

The abdominal cavity contains solid and hollow organs that make up the GI, genital, and urinary systems (**FIGURE 20-1**). Solid organs include the liver, spleen, pancreas, kidneys, and ovaries (in women). Technically, organs such as the kidneys, ovaries, and most of the pancreas are retroperitoneal (behind

the peritoneum). However, because they are located next to the peritoneum, they can cause abdominal pain. An injury to a solid organ can cause shock and bleeding because of the amount of blood vessels that the organ contains.

The Gastrointestinal System

The main function of the GI system, which is also known as the digestive tract, is to absorb the products of digestion to fuel the cells within the body. This system consists of the mouth, salivary glands, pharynx, esophagus, stomach, intestines, liver, gallbladder, pancreas, rectum, and anus. It is covered in detail in Chapter 7, *The Human Body*.

The entire digestion process takes 8 to 72 hours. It begins when food is put into the mouth and chewed. The salivary glands secrete saliva to help lubricate the food, allowing it to be more easily swallowed. Saliva also contains enzymes that begin the chemical breakdown of foods, particularly starches (and some initial breakdown of triglycerides). These complex carbohydrates can be disassembled into simple sugars that are more easily absorbed.

Once food is swallowed, it moves through the esophagus. The esophagus does not absorb nutrients but rather pushes the food along using rhythmic contractions called **peristalsis**. The esophagus passes through the diaphragm and food comes to the sphincter located at the junction of the

FIGURE 20-1 The solid and hollow organs of the abdomen. **A.** Solid organs include the liver, spleen, pancreas, kidneys, and ovaries (in women). **B.** Hollow organs include the gallbladder, stomach, small intestine, large intestine, and bladder.

© Jones & Bartlett Learning.

esophagus and the stomach. The cardiac sphincter is designed to prevent food from backing up into the esophagus.

Intertwined around the esophagus are veins that drain into an even more complex series of veins, which ultimately join to form the **portal vein**. The portal vein transports venous blood from the GI tract directly to the liver for processing of the nutrients that have been absorbed. If blood flow through the liver slows for any reason, the blood may back up throughout the entire GI system because this series of veins lacks any valves. The veins surrounding the stomach and esophagus then become dilated. Even a low amount of pressure may cause leaking or rupture of these vessels.

As the food enters the stomach, this muscular organ begins to secrete hydrochloric acid, which

helps to break down the food to a form that can be used by the body. To mix the acid with the food more evenly, the stomach also contracts, churning the acid and food mixture together until a relatively smooth consistency is achieved. The stomach absorbs some substances, such as water, alcohol, caffeine, and some medications. Once the food is thoroughly converted, a semisolid mass called chyme exits the pyloric sphincter, the doorway at the inferior portion of the stomach.

The main function of the GI system is revealed in the next portion of the GI system, the duodenum, where the GI system begins to absorb resources for use by other cells in the body.

The duodenum is the first part of the small intestine. It is where the pancreas, liver, and gallbladder connect to the digestive system. The stomach is

YOU are the Provider

Part 1

You are dispatched to a local dialysis clinic for a patient who “needs transport to the emergency department.” On arrival, you are greeted by clinic staff, who state that the patient undergoes dialysis every Monday, Wednesday, and Friday because of anuria, and today (Monday) when he came in, he “wasn’t acting right” and seemed a little short of breath. The clinic staff tells you that they are unable to perform dialysis on this patient until his mental status improves.

1. What are some potential causes of altered mental status in a patient receiving dialysis?
2. On the basis of the information provided, which type of dialysis does this patient receive?
3. What is anuria?

designed to release only small amounts of the food into the duodenum, thereby enabling the small intestine to better manage digestion. The exocrine portion of the pancreas secretes several enzymes into the duodenum that assist with digestion of fats, proteins, and carbohydrates. Amylase, which breaks down starches into sugar, is one enzyme the pancreas secretes. The pancreas also produces bicarbonate and insulin. Bicarbonate neutralizes the stomach acid in the duodenum, and insulin helps regulate the levels of glucose in the bloodstream.

The liver assists in digestion by secreting bile. Bile is used by the body to help break down fats. The liver also filters toxic substances produced by digestion, creates glucose stores, and produces substances necessary for blood clotting and immune function. The gallbladder is a hollow pouch located beneath the liver that acts as a reservoir for bile.

The small intestine, where 90% of absorption occurs, produces enzymes that work with the pancreatic enzymes to turn chyme into substances that can be directly absorbed by the capillaries of the small intestine and thereby move into the bloodstream. Blood filled with these nutrients exits the intestinal circulation and heads to the liver, where additional metabolism of fats and proteins takes place. The blood then leaves the liver and enters the hepatic veins. Water-soluble vitamins are absorbed into the bloodstream for use by cells.

Words of Wisdom

The liver affects the GI system indirectly, through carbohydrate metabolism. Brain cells can burn only one fuel source—glucose. If the blood glucose level falls, the liver can convert glycogen into glucose. Dramatic drops in blood glucose level will cause the liver to convert fats and proteins into sugar. As blood flows through the liver, fat and protein metabolism continues. Without a functioning liver, a person would soon die because they would not be able to use any of the proteins that were absorbed from the GI system. In addition, the liver detoxifies drugs, completes the breakdown of dead red and white blood cells, stores vitamins and minerals, and makes clotting factors.

The jejunum, the next part of the small intestine, comprises a large amount of the surface area of the small intestine and does much of the work. The final part of the small intestine is the ileum.

The ileum absorbs nutrients that were not absorbed earlier. It also absorbs bile acids so they can be returned to the liver for future use and vitamin B₁₂ for making nerve cells and red blood cells.

The large intestine, or colon, is the next destination. Substances not broken down and used as nutrients enter the colon as waste products, or feces. The primary role of the large intestine is to complete the reabsorption of water. Water is absorbed, which helps to solidify the digested material, and stool is formed. Although most water is reabsorbed in the small intestine, the osmotic function within the colon helps to solidify the digested material into a formed stool. The colon is also the site of bacterial digestion. Bacteria normally found within the colon help to finish the breakdown of the chyme. This breakdown produces gas as a by-product. Flatulence may be considered impolite, but it is certainly normal.

Attached to the last portion of the colon is the rectum. The colon terminates at the anus, where the feces are expelled from the body.

Additional Abdominal Organs

The spleen is also located in the abdomen but has no digestive system function. The spleen is part of the lymphatic system and plays a significant role in relation to red blood cells and the immune system. It assists in the filtration of blood, aids in the development of red blood cells, and serves as a blood reservoir. The spleen also produces antibodies to help the body fight off disease and infection.

The Genital System

The abdominal space also holds the male and female reproductive organs. The male reproductive system consists of the testicles, epididymis, vasa deferentia, seminal vesicles, prostate gland, and penis. The female reproductive system includes the ovaries, fallopian tubes, uterus, cervix, and vagina.

The Urinary System

The urinary system consists of the kidneys, which filter the blood and produce urine; the urinary bladder, which stores the urine until it is released from the body; the ureters, which transport the urine from the kidneys to the bladder; and the urethra, which transports the urine from the bladder

FIGURE 20-2 The urinary system. **A.** Anterior view showing the relationship of the kidneys, ureters, urinary bladder, and urethra. **B.** Cross section of the human kidney.

© Jones & Bartlett Learning.

out of the body (**FIGURE 20-2**). Overall, the urinary system performs two main functions for the body: (1) it regulates electrolytes, water content, and acids in the blood; and (2) it removes metabolic wastes,

drug metabolites, and excess fluids. The kidneys perform these functions continuously, filtering 200 L of blood each day. In addition, the kidneys produce hormones that generate new red blood cells and help the liver convert glycogen to glucose. Nephrons, found in the cortex, are the structural and functional units of the kidney that form urine. Each kidney contains approximately 900,000 to 1 million nephrons, although these numbers can vary dramatically.¹

The kidneys play a major role in maintaining homeostasis, including calcium, magnesium, and phosphate balance. They preserve this balance by eliminating metabolic waste products such as urea from the blood. When the kidneys fail, the patient loses the ability to excrete urea from the body, leading to a condition called **uremia**. Urea that is normally excreted through the kidneys then builds up in the blood.

Once the urine enters the collecting ducts, it passes through the minor calyx, into the major calyx, and then into the renal pelvis. From there, the urine moves through the ureter (one ureter from each kidney) and is stored in the urinary bladder. Normally, the brain exerts control over the urge to void, keeping the external urinary sphincter contracted until conditions are favorable for urination. At this point, the inhibition of the external urinary sphincter is reduced and the urine passes from the urinary bladder into the urethra.

The beginning of the urethra, through which urine is expelled, sits at the inferior aspect of the bladder. In females, the urethra exits at the site of the external genitalia. The female urethra is shorter than the male urethra (1.5 versus 8 inches [4 versus 20 cm]).

Words of Wisdom

The normal adult forms 1.5 to 2 L of urine per day.

Pathophysiology

Acute abdomen is a medical term referring to the sudden onset of abdominal pain that indicates an irritation of the **peritoneum**, the thin membrane that lines the entire abdominal cavity. This condition, called **peritonitis**, can be caused by an infection, a penetrating abdominal wound, a blunt

injury severe enough to damage abdominal organs, and many diseases. In all cases, the major symptom is the same: severe pain. The major clinical signs are abdominal tenderness and distention.

Anatomically, the peritoneum is not one membrane, but two. The parietal peritoneum lines the walls of the abdominal cavity; the visceral peritoneum covers the surface of each of the organs in the abdominal cavity.

Two different types of nerves supply these two areas of the peritoneum. The parietal peritoneum is supplied by the same nerves from the spinal cord that supply the skin overlying the abdomen; it can therefore perceive many of the same sensations—pain, touch, pressure, heat, and cold. These sensory nerves can easily identify and localize a point of irritation. In contrast, the visceral peritoneum is supplied by the autonomic nervous system. These nerves are far less able to localize sensation. The visceral peritoneum is stimulated when distention or contraction of the hollow abdominal organs activates the stretch receptors. This sensation is usually interpreted as **colic**, a severe, intermittent cramping pain.

When receptors at the affected organs are stimulated, they send impulses along the nerves to the brain, where the impulses are evaluated and interpreted as pain. **Visceral pain**—the type of pain most commonly associated with urologic problems—usually occurs when receptors in the hollow structures, such as the ureters, urinary bladder, and urethra, are stimulated. Pinpointing the source of such pain is challenging because only a few nerve fibers may be involved in the pain transmission. Because many different nerve fibers travel to the brain through the spinal cord, pain that originates in one area of the body (eg, the urinary bladder) may be perceived by the brain as coming from a different area of the body (eg, the neck or shoulder). Other painful sensations that occur because of an irritated visceral peritoneum may be perceived at a distant point on the surface of the body, such as the back or shoulder. This phenomenon is called **referred pain**.

Referred pain is the result of connections between the body's two separate nervous systems. The spinal cord supplies sensory nerves to the skin and muscles; these nerves are a part of the somatic (voluntary) nervous system. The autonomic nervous system controls the function of the abdominal organs and the caliber of the blood vessels. The nerves connecting these two systems cause

FIGURE 20-3 Acute cholecystitis can cause referred pain to the shoulder, as well as abdominal pain.

© Jones & Bartlett Learning.

the stimulation of the autonomic nerves to be perceived as stimulation of the spinal sensory nerves. For example, acute cholecystitis (inflammation of the gallbladder) may cause referred pain to the right shoulder because the autonomic nerves serving the gallbladder lie near the spinal cord at the same anatomic level as the spinal sensory nerves that supply the skin of the shoulder² (**FIGURE 20-3**).

Peritonitis typically causes **ileus**, or paralysis of the muscular contractions that normally propel material through the intestine (peristalsis). The retained gas and feces, in turn, cause abdominal distention. In the presence of such paralysis, nothing that is eaten can pass normally out of the stomach or through the bowel. The only way the stomach can empty itself is by **emesis** or by vomiting. For this reason, peritonitis is almost always associated with nausea and vomiting. These complaints do not point to a specific cause because they can accompany almost every type of GI disease or injury.

Peritonitis is associated with a loss of body fluid into the abdominal cavity. Abnormal shifts of fluid from the bloodstream into body tissues decrease the volume of circulating blood and may eventually cause hypovolemic shock. This problem can be compounded by massive internal or external bleeding, resulting in severe inadequate perfusion (shock). The patient may have normal vital signs or, if the peritonitis has progressed further, signs

TABLE 20-1 Common Abdominal Conditions

Condition	Localization of Pain
Appendicitis	Around navel (referred); right lower quadrant (direct); rebound tenderness (pain felt on the rebound after palpation)
Cholecystitis	Right shoulder (referred); right upper quadrant (direct)
Ulcer	Upper midabdomen or upper back area
Diverticulitis	Left lower quadrant
Abdominal aortic aneurysm (ruptured or dissecting)	Low part of back and lower quadrants
Cystitis (inflammation of the bladder)	Lower midabdomen (retropubic)
Kidney infection (pyelonephritis)	Costovertebral angle
Kidney stone	Right or left flank, radiating to genitalia (referred)
Pelvic inflammation (in women)	Both lower quadrants
Pancreatitis	Upper abdomen (both quadrants); back
Pneumonia	Referred pain to the upper abdomen
Hernia	Anywhere in the abdominal area
Peritonitis	Anywhere in the abdominal area

© Jones & Bartlett Learning.

of shock (such as restlessness, tachycardia, and hypotension). When peritonitis is accompanied by hemorrhage, the signs of shock are much more apparent.

Fever may or may not be present, depending on the cause of the peritonitis. Patients with **diverticulitis** (an inflammation of small pockets in the colon) or **cholecystitis** (inflammation of the gallbladder) may have a substantial elevation in temperature, which may be due to the inflammatory process itself or an underlying infection. However, patients with acute **appendicitis** may have a normal temperature until the appendix ruptures and an abscess starts to form.

Diseases and conditions of the renal and urologic systems range from mild (urinary tract infections) to true emergencies (acute kidney injury). Although the prehospital care for many urologic diseases is supportive, your ability to recognize the signs and symptoms of these conditions, especially when they are genuine emergencies, is critical to providing your patients with the best chance of a positive outcome. The most common abdominal emergencies, with the most common locations of direct and referred pain, are listed in **TABLE 20-1**.

TABLE 20-2 Conditions That May Cause or Lead to Urinary Retention

Kidney stones
Benign prostate hypertrophy
Urethral obstructions
Urinary tract infections
Nerve damage

Data from Urinary Retention. National Institute of Diabetes and Digestive and Kidney Diseases website. www.niddk.nih.gov/health-information/urologic-diseases/urinary-retention. Accessed September 15, 2017; and Urinary Retention. Baylor College of Medicine website. www.bcm.edu/healthcare/care-centers/obstetrics-gynecology/conditions/urinary-retention. Accessed September 15, 2017.

Many conditions discussed in this section can cause **urinary retention**—that is, incomplete emptying of the bladder or a complete lack of ability to empty the bladder. Some of these conditions are listed in **TABLE 20-2**.

Causes of Acute Abdomen

The entire abdominal cavity normally contains a very small amount of peritoneal fluid that bathes and lubricates the organs. Any condition that allows

pus, blood, feces, urine, gastric juice, intestinal contents, bile, pancreatic juice, amniotic fluid, or other foreign material to accumulate within or adjacent to this cavity can cause peritonitis and, therefore, an acute abdomen. Technically, organs such as kidneys, ovaries, and other genitourinary structures are retroperitoneal (behind the peritoneum). However, because they lie next to the peritoneum, problems in these organs can result in an acute abdomen. Ultimately, almost every kind of abdominal problem can cause an acute abdomen.

Gastrointestinal Hemorrhage

Bleeding within the GI tract is a symptom of a disease, not a disease itself. GI hemorrhage can be acute, which may be shorter in duration and more severe, or chronic, which may be longer in duration and less severe. All complaints of bleeding from the GI tract should be considered serious. Causes of GI bleeding are shown in **TABLE 20-3**.

A GI hemorrhage can occur in the upper or lower GI tract. The upper GI tract spans from the esophagus to the upper part of the small intestine.

In the esophagus, bleeding conditions might stem from esophagitis, esophageal varices, or a Mallory-Weiss tear, which results from excessive retching or vomiting. **Hematemesis** (vomiting blood) is frequently seen in patients with upper GI bleeding. The blood is either bright red or has the appearance of coffee grounds, depending on where in the GI tract it originated and how briskly it is occurring. Upper GI bleeding may also manifest as **melena** (dark tarry stools), as a result of partial digestion of the blood.

The lower GI tract spans the upper part of the small intestine to the anus. Bowel inflammation, diverticulosis, diverticulitis, cancer, and hemorrhoids are common causes of bleeding in the lower GI tract. In lower GI tract bleeding, the blood is often bright red unless it is coming from higher up in the digestive tract.

Esophagitis

As its name suggests, **esophagitis** is an inflammation of the esophagus. This can be caused by an infectious process or by reflux of gastric secretions into the esophagus. Additionally, some medications

Organ	Causes	Location	Substances
Esophagus	Inflammation (esophagitis) Varices Mallory-Weiss tear Cancer Dilated veins (cirrhosis, liver disease) Gastroesophageal reflux disease	Upper GI bleed	Melena, hematemesis, vomitus with gross blood
Stomach	Ulcers Cancer Inflammation (gastritis)	Upper GI bleed	Melena, hematemesis, vomitus with gross blood
Small intestine	Ulcer (duodenal) Cancer Inflammation (irritable bowel disease)	Upper or lower GI bleed	Melena, hematemesis, vomitus with gross blood
Large intestine	Infections Inflammation (ulcerative colitis) Colorectal polyps Colorectal cancer Diverticular disease	Lower GI bleed	Hematochezia
Rectum	Hemorrhoids	Lower GI bleed	Hematochezia, gross bleeding

Abbreviation: GI, gastrointestinal

can be irritating, as can chemotherapy or radiation therapy. Esophagitis also is associated with eosinophils, a type of white blood cell.

Regardless of the underlying cause, the effects are irritation and swelling. In general, patients will present with either heartburn or choking as their primary complaint. Esophagitis most commonly occurs in patients with gastroesophageal reflux disease, discussed next.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a condition in which the sphincter between the esophagus and the stomach opens, allowing stomach acid to move superiorly. This condition, which is also referred to as acid reflux disease, can cause a burning sensation within the chest (heartburn). Various factors can make some people more susceptible to this condition. Smoking, obesity, and pregnancy all increase the chances of GERD. Eating fatty fried foods, drinking alcohol, and eating citrus fruits are also factors that are associated with GERD. If the reflux continues over a long period, damage can occur to the esophageal wall. This damage could result in weakened portions that are more susceptible to bleeding.

Heartburn is the predominant clinical finding for this condition. This pain may be increased with positional changes: sitting upright is preferred, whereas lying flat makes the condition worse. Some patients may not have pain, but experience coughing or have difficulty swallowing. Bleeding can occur if the damage is long term, resulting in hematemesis and melena.

Peptic Ulcer Disease and Gastritis

Both the stomach and the duodenum are subjected to high levels of acidity. High levels of acidity can result in **ulcers**, which are abrasions of the stomach or small intestine. To prevent damage to these organs, protective layers of mucus line both organs. In peptic ulcer disease (PUD), this protective layer is eroded, allowing the acid to eat into the organ itself over the course of weeks, months, or even years. **Gastritis** is caused by the same imbalance between stomach acid and the protective layers. Gastritis is a preulcerative state in which the stomach is inflamed, but erosions have not yet occurred.

Most peptic ulcers are the result of infection of the stomach with *Helicobacter pylori*. Another major cause is erosive gastritis, often resulting from chronic use of nonsteroidal anti-inflammatory

YOU are the Provider

Part 2

As you begin to interview the patient, you find that he is able to answer all questions appropriately; however, he is very slow to formulate his answers. According to the patient and staff, the patient is normally as “sharp as a tack,” and this delay in responding is abnormal for him. The patient denies engaging in any abnormal activities over the weekend but states that he went to his granddaughter’s birthday party on Saturday and may have overexerted himself.

Recording Time: 1 Minute

Appearance	Pale; “sick” looking
Level of consciousness	Alert; oriented to person, place, time, and event; however, slow to respond to questions
Airway	Patent
Breathing	36 breaths/min; normal rhythm
Circulation	Bounding radial pulses; skin warm and dry

4. The patient seems to be answering all questions appropriately, but more slowly than what is reported to be normal. Should you approach the dialysis staff and request that he undergo dialysis to help improve his mental status?
5. You note a “lump” in the patient’s left forearm. What is this lump, and why is it important for you to note?

drugs (NSAIDs). In erosive gastritis, the mucosal lining of the stomach slowly erodes and ulcerates. Alcohol and smoking can also affect the severity of these conditions by increasing gastric acidity.

PUD affects men and women equally, but tends to occur more often in older age groups. As people age, the immune system's ability to fight infection decreases, making infection more likely. The geriatric population, in general, also uses NSAIDs more frequently for arthritis and other age-related musculoskeletal conditions.

All factors cited for PUD can also cause gastritis. Foodborne infections and food allergies also can cause inflammation of the stomach.

Patients with peptic ulcers and gastritis experience a classic sequence of burning or gnawing pain in the stomach that subsides or diminishes immediately after eating and then reemerges 2 to 3 hours later. The pain usually presents in the upper abdomen, but sometimes may be found below the sternum. With some patients, the pain occurs immediately after eating. Nausea, vomiting, belching, and heartburn are common symptoms. If the erosion is severe, gastric bleeding can occur, resulting in hematemesis and melena.

Some ulcers heal without medical intervention, but complications often can occur from bleeding or perforation (a hole through the wall of the stomach). More serious ulcerative conditions can cause severe peritonitis and an acute abdomen.

Mallory-Weiss Tear

A **Mallory-Weiss tear** is a tear in the junction between the esophagus and the stomach, causing severe bleeding and potentially death. Primary risk factors include alcoholism and eating disorders. Mallory-Weiss tears have a sudden onset and affect people of any age.

Violent coughing or vomiting are the principal causes of a Mallory-Weiss tear. In women, this syndrome may be associated with severe vomiting related to pregnancy. The extent of the bleeding can range from very minor bleeding, resulting in very little blood loss, to severe bleeding and extreme fluid loss. In extreme cases, patients may experience signs and symptoms of shock, upper abdominal pain, hematemesis, and melena.

Similar to a Mallory-Weiss tear, **Boerhaave syndrome** also occurs during vomiting. In this case, the esophagus tears longitudinally and the tear

travels entirely through the wall of the esophagus. This creates a passage for blood, air, and food out of the esophagus into the mediastinum. Occurring more often in men, Boerhaave syndrome typically presents after a large meal that included alcohol consumption.

Esophageal Varices

Esophageal varices occur when the amount of pressure within the blood vessels surrounding the esophagus increases. The esophageal blood vessels eventually drain their blood into the liver. If the liver becomes damaged and blood cannot flow through it easily, blood begins to back up into these portal vessels, dilating the vessels and causing the capillary network of the esophagus to begin leaking. If pressure continues to build, the vessel walls may fail, causing massive upper GI bleeding and, quickly afterward, hematemesis.

In industrialized countries, alcohol is the main cause of portal hypertension. Long-term alcohol consumption damages the interior of the liver (cirrhosis), leading to slower blood flow. In developing countries, viral hepatitis is the main cause of liver damage.

Presentation of esophageal varices takes two forms. Initially, the patient shows signs of liver disease—fatigue, weight loss, jaundice, anorexia, edema in the abdomen, abdominal pain, nausea, and vomiting. This disease process is gradual and can take months to years for the patient to reach a state of extreme discomfort.

By contrast, rupture of the varices occurs far more suddenly. The patient may report sudden-onset discomfort in the epigastric region or sternum and may have severe difficulty swallowing, vomiting of bright-red blood, hypotension, and signs of shock. If the bleeding is less dramatic, hematemesis and melena are likely. Regardless of the rate of bleeding, damage to these vessels can be life threatening. Spontaneous rupture is often life threatening, and significant blood loss at the scene may be evident. Major ruptures can lead to death in a matter of minutes.

Hemorrhoids

Hemorrhoids are created by swelling and inflammation of the blood vessels surrounding the rectum. They are a common problem, with almost one-half

the population having at least one hemorrhoid by age 50 years.³ Hemorrhoids may result from conditions that increase pressure on the rectum or from irritation of the rectum. Pregnancy, straining at stool, and chronic constipation cause increased pressure. Diarrhea can cause irritation.

Hemorrhoids present as bright-red blood during defecation. This bleeding, which is called **hematochezia**, tends to be minimal and is easily controlled. Additionally, patients may experience itching and a small mass on the rectum. Typically, this mass is a clot formed in response to the mild bleeding.

Nonhemorrhagic Conditions

Gallstones

The gallbladder is a storage pouch for digestive juices and waste from the liver. Gallstones can form and block the outlet from the gallbladder, causing pain. Sometimes the blockage will pass. If it does not, it can lead to inflammation of the wall of the gallbladder, called cholecystitis. In severe cases, the gallbladder may rupture, causing inflammation to spread and irritate surrounding structures such as the diaphragm and bowel. This condition presents as a constant, severe pain in the right upper or midabdominal region that may refer to the right upper back, shoulder area, or flank. The pain may steadily increase for hours, or it may come and go. Cholecystitis commonly produces symptoms about 30 minutes after consumption of a particularly fatty meal and usually at night. Other symptoms include general GI distress such as nausea and vomiting, indigestion, bloating, gas, and belching.

Special Populations

Older adults may not present with the normal signs and symptoms of cholecystitis. Localized tenderness may be the only finding. Thorough questioning during your assessment may help lead you to a possible differential diagnosis of gallbladder involvement. If your patient is stable, take a few extra moments to ask clarifying questions regarding current symptoms, past medical history, and medications. Remember to ask about any over-the-counter medications or herbal remedies the patient may have taken.

Pancreatitis

The pancreas forms digestive juices and is also the source of insulin. Inflammation of the pancreas, called **pancreatitis**, can be caused by an obstructing gallstone, alcohol abuse, and other diseases. Severe pain may present in the upper left and right quadrants and often radiates to the back. Other signs and symptoms may include nausea and vomiting, abdominal distention, and tenderness. Complications such as sepsis or hemorrhage can occur, in which case assessment may also reveal fever or tachycardia.

Appendicitis

The appendix is a small recess in the large intestine. Inflammation or infection in the appendix is called appendicitis and is a frequent cause of acute abdomen. This inflammation can eventually cause the tissues to die and/or rupture, causing an abscess, peritonitis, or shock. Initially, the pain caused by appendicitis is generalized, dull, and diffuse and may center in the umbilical area. The pain later localizes to the right lower quadrant of the abdomen. Appendicitis can also cause referred pain. In addition, the patient may report nausea and vomiting, anorexia (lack of appetite for food), fever, and chills.

A classic symptom of appendicitis is **rebound tenderness**. Rebound tenderness is a result of peritoneal irritation. This can be assessed by pressing down gently and firmly on the abdomen—the patient will feel pain when the pressure is released. Women who are pregnant may not exhibit this symptom.

Gastroenteritis

Acute **gastroenteritis** comprises a family of conditions revolving around a central theme of infection combined with diarrhea, nausea, and vomiting. Bacterial and viral organisms can cause this condition. These organisms typically enter the body through contaminated food or water. Patients may begin to experience an upset stomach and diarrhea as soon as several hours or several days after contact with the contaminated matter. The disease can then run its course in 2 to 3 days or continue for several weeks.

Gastroenteritis may also be caused by non-infectious conditions such as adverse reactions to medications, exposure to certain toxins, or

Special Populations

Appendicitis can be difficult to diagnosis. Consider that appendicitis occurs most often in young people, even young women who are pregnant. As the uterus expands to accommodate the growing fetus, it moves the appendix out of its normal position. A woman in her third trimester of pregnancy will more likely present with upper right quadrant or right flank pain instead of lower right pain if she has appendicitis. Even the most attentive paramedic will have difficulty determining if this pain is appendicitis, cholecystitis, or kidney stones (renal calculi).

chemotherapy. The symptoms are similar regardless of the underlying cause.

Diarrhea is the principal symptom in both infectious and noninfectious gastroenteritis. Patients may experience large dumping-type diarrhea or frequent small liquid stools. The diarrhea may contain blood and/or pus, and it may have a foul odor or be odorless. Abdominal cramping is frequently reported. Nausea, vomiting, fever, and anorexia are also present. If the diarrhea continues, dehydration will result. As the volume of fluid loss increases, the likelihood of shock increases.

Safety

Infection from the bacterium *Clostridioides difficile* (commonly referred to as *C diff*) presents with GI symptoms including liquid diarrhea and colitis. *C difficile* is easily spread from one patient to another if proper hand hygiene is not employed and proper decontamination is not executed after each call.

Transmission of *C difficile* occurs in susceptible patients by contact with surfaces contaminated with feces. The bacterium can occasionally be transmitted to patients by contact with the unwashed hands (or contaminated gloves) of health care providers. Infections with *C difficile* are generally related to use of antibiotics in patients who are being treated for other infections. The antibiotics disrupt the normal flora in the intestines and allow for an overgrowth of the *C difficile* bacteria.

C difficile is not inactivated by alcohol-based hand products. Glove use, good handwashing, and cleaning of contaminated surfaces with a chlorine-based cleaning agent are important in preventing the spread of the bacterium.

Diverticulitis

Diverticulitis was first recognized around 1900, when the types of foods people ate began to change dramatically. In particular, the amount of fiber within the US diet plummeted as the amount of processed foods eaten increased.

As the amount of fiber consumed as part of the diet decreases, the consistency of the normal stool becomes more solid. This hard stool requires more intestinal contractions to expel, subsequently increasing pressure within the colon. In this environment, small defects within the colonic wall that would otherwise never pose a problem now fail, resulting in bulges in the wall. These small outcroppings eventually turn into pouches, called diverticula. As feces travel through the colon, some may become trapped within these pouches. When bacteria grow there, they cause localized inflammation and infection.

The main symptom of diverticulitis is abdominal pain, which tends to be localized to the left side of the lower abdomen. Classic signs of infection include fever, malaise, body aches, chills, nausea, and vomiting. Bleeding is rare with this condition. Because of the local infections of these pouches, adhesions may develop, narrowing the diameter of the colon and resulting in constipation and bowel obstruction. In severe cases, these infected outcroppings may burst, causing perforation of the affected segment of colon. This event may result in peritonitis, severe infection, and, if left untreated, septic shock.

Chronic Inflammatory Conditions

Ulcerative Colitis

Ulcerative colitis is caused by inflammation of the colon. This inflammation is generalized, affecting the inner lining of the intestine, and does not occur in patches, as in Crohn disease. It is unclear what causes the chronic inflammation, though genetics, stress, and autoimmunity have been speculated to be responsible. In ulcerative colitis, the inflammation causes a thinning of the wall of the intestine, resulting in a weakened, dilated rectum. The damaged lining of the colon is highly susceptible to infections by bacteria and bleeding. These two states

Special Populations

Many of the conditions discussed in this chapter are more prevalent in older patients. Older patients can have diminished abilities to detect pain; as a result, they may not display rigidity or guarding. This presentation can hamper diagnosis and, more importantly, delay access to health care. Because an older patient has decreased body temperature regulation and response, conditions such as an acute abdomen, including peritonitis, may not present with fever. Even if fever is present, it can be minimal. If an older patient does not feel pain, the patient may not know why a fever has occurred. The patient may try to treat it at home. Thus, by the time emergency medical services (EMS) is activated, the patient is already septic and seriously ill.

Abdominal pain can also be a symptom of a cardiac condition. Imagine how difficult it would be to initially distinguish the source of abdominal pain in a 75-year-old man with a history of gastric ulcers, diverticulitis, and heart disease. Additionally, vascular pathology such as an abdominal aortic aneurysm can cause abdominal pain.

Comorbidity creates great difficulties for health care providers, but success can be achieved by obtaining a complete history and performing a thorough physical examination. You should ask about the patient's medical history, especially the history of recent illness, to identify a potential illness. Ask about abdominal discomfort, when the patient last had a bowel movement, whether the patient was constipated or had diarrhea, when the patient last ate, and whether the patient vomited. Asking these questions can help to rule out appendicitis, bowel obstruction, and ruptured bowel. Remember, however, that history taking should not delay transport.

Consider establishing intravenous (IV) access in most patients with abdominal pain who have comorbid factors. Finally, monitor vital signs, provide rapid transport, and be ready for any changes in the patient's status.

establish the foundation on which the signs and symptoms develop.

In the United States, approximately 1 million people have ulcerative colitis.⁴ In the past, ulcerative colitis was thought to peak between age 15 and 25 years and then again between 55 and 65 years, although studies contradict this supposition.^{5,6} It occurs more often in men than in women.⁷ There is a strong family history component for this disease.

For example, having a sibling with ulcerative colitis increases the risk of developing the disease more than fourfold.⁸ This fact supports the hypothesis that genetics plays some role in this disease. Ulcerative colitis is more prevalent in Caucasians and people of Ashkenazi Jewish descent.⁷

The presentation of this condition is characterized by gradual onset of bloody diarrhea, hematochezia, and mild to severe abdominal pain. Other signs and symptoms can be joint pain and skin lesions. These effects lend credence to the idea of an autoimmune component to the disease. Finally, the patient can experience fever, fatigue, and loss of appetite from the infection.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a condition in which patients have abdominal pain and changes in their bowel habits. One diagnostic criterion is that patients have pain at least 3 days per month for at least 3 months. The pathology of the disease is unclear. The following three main factors are typically observed in patients with IBS:

- Hypersensitivity of bowel pain receptors. Normal stretching of the bowel can cause pain in these patients.
- Hyperresponsiveness of the smooth muscles in the bowel, which produces the cramping sensations and diarrhea.
- Psychiatric disorder connection and IBS. It is unclear if the bowel disorder causes the psychiatric disorder, or vice versa.

Hyperresponsiveness of the bowel in IBS can cause areas of spasm. These spasms can stop fecal movement, creating constipation and bloating. Conversely, if the spasms are more wavelike than localized, the patient can experience diarrhea as the feces are moved quickly through the bowel.

Patients typically begin to have problems with bowel habits during childhood, with 50% of IBS cases developing in patients younger than age 35 years.⁹ In Western countries, women are more susceptible to this disease; in contrast, in South Asia, South America, and Africa, the typical patient is a man.¹⁰

IBS can be triggered by various stimuli. Stress, large meals, and certain foods such as wheat, rye, chocolate, alcohol, milk products, and caffeinated drinks can trigger an attack.

IBS is a chronic condition. Prehospital presentations will typically involve a flare-up of the condition. Patients may present with abdominal pain or discomfort. This pain is relieved by a bowel movement. When the pain starts, there is usually a change in the frequency and consistency of bowel movements. Patients may experience diarrhea, **steatorrhea**, or constipation. They may also feel bloated.

Crohn Disease

Crohn disease is similar to ulcerative colitis, but can involve the entire GI tract from mouth to anus. The main part of the GI tract that tends to be affected is the ileum, the last portion of the small intestine before it joins the large intestine. There are several theories as to the cause of Crohn disease, though no definitive cause has been identified.

Although Crohn disease is not as common as ulcerative colitis, it affects hundreds of thousands of Americans.⁴ Most patients are between age 15 and 35 years,¹¹ although a second peak in incidence among older adults (age 60 to 70 years) has also been identified.¹² Men are diagnosed as often as women.¹¹ This condition generally affects more whites than African Americans, and people of Ashkenazi Jewish descent have a notably increased incidence of the disease.¹³

Of interest with Crohn disease and colitis is the presence of signs and symptoms outside the GI system. This evidence helps to support the theory that an autoimmune component is functioning within this disease. It is unclear what causes this immune reaction: Does the presence of antigens in the GI tract trigger an immune response? Is the immune system itself not working correctly? Another theory is that the immune system creates antibodies for an antigen that does not exist, thereby triggering a cascade of reactions to a nonexistent invader.

Family history and genetics play a role with this disease. Medical researchers are discovering that how the body is made and how it is able to function are important characteristics in whether a person gets a disease and how that disease progresses. The fact that many people with Crohn disease have family members who have some type of bowel disease suggests a familial/genetic component.¹⁴

Regardless of the underlying reason for the development of Crohn disease, the result is a series of attacks by the immune system on the GI tract. This

activity of white blood cells damages all layers of the portion of GI tract involved. The result is most often a scarred, narrowed, stiff, and weakened portion of the small intestine. This patch of damage is found among areas of intestine that are normal, and narrowing of this segment can cause bowel obstruction.

Patients with Crohn disease present with a chronic complaint of abdominal pain, often in the lower right area. This pain corresponds to the location of the ileum. Rectal bleeding, weight loss, diarrhea, arthritis, skin problems, and fever may also be present. Bleeding tends to involve small blood losses over a long period of time. Acute severe hemorrhage is rare, but chronic bleeding resulting in anemia and hypotension does occur. Patients can have episodes of mild to severe signs and symptoms.

Pathophysiology of the Urinary System

Diseases and conditions of the urinary system can cause acute abdominal pain. These conditions range from mild (urinary tract infections) to true emergencies (acute kidney injury). Although the prehospital care for many urologic diseases is supportive, your ability to recognize the signs and symptoms of the true emergencies is critical to providing your patients with the best chance of a positive outcome.

Urinary tract infections (UTIs), also known as bladder inflammation or **cystitis**, usually develop in the lower urinary tract (urethra and bladder) when either normal bacteria flora, which exist naturally on the skin, or other bacteria enter the urethra and grow. These infections are common, especially in women, owing to the relatively short urethra and the proximity of the urethra to the vagina and rectum. A UTI in the upper urinary tract (ureters and kidneys) occurs most often when a UTI in the lower urinary tract remains untreated. Upper UTIs can lead to **pyelonephritis** (inflammation of the kidney and renal pelvis) and abscesses, which eventually reduce kidney function. In severe cases, and more commonly in the elderly, untreated UTIs can lead to sepsis.

Common symptoms in patients with a lower UTI include painful urination, frequent urges to urinate, and difficulty in urination. The pain usually begins as a visceral discomfort but then converts to

an extreme burning pain, especially during urination. The pain, which remains localized in the pelvis, is often perceived as bladder pain in women and as prostate pain in men. Sometimes the pain may be referred to the shoulder or neck. In addition, the urine may have a foul odor or may appear cloudy.

Pathophysiology of the Renal System

Kidney Stones

Kidney stones (renal calculi) originate in the renal pelvis and arise when an excess of insoluble salts or uric acid crystallizes in the urine (**FIGURE 20-4**). This excess of salts is typically due to water intake that is insufficient to dissolve the salts. The stones consist of different types of chemicals, depending on the precise imbalance in the urine.

The most common stones—calcium stones—occur more frequently in men than in women and may have a hereditary component. These stones also occur in patients with metabolic disorders such as gout or with hormonal disorders.

Patients who have kidney stones will almost always be in pain. (Many rate kidney stone pain as 11 on a scale of 1 to 10.) The pain usually starts as a vague discomfort in the flank but becomes very intense within 30 to 60 minutes. It may migrate forward and toward the groin as the stone passes through the system.

Some patients will be agitated and restless as they walk and move in an attempt to relieve the pain. Others will attempt to remain motionless and guard

the abdomen. Either behavior makes palpation of the abdomen difficult. Vital signs will vary, depending on the severity of pain. The greater the pain, the higher the blood pressure and pulse will be.

If a stone has become lodged in the lower part of the ureter, signs and symptoms of a UTI (frequency and urgency of urination, painful urination, and/or **hematuria**) may be present, but the patient will not have a fever. If a kidney stone is suspected, be sure to obtain a patient history and a family history; both can supply important information.

Kidney Disease

Kidney disease may be categorized as either acute or chronic. In the United States, the prevalence of chronic kidney disease is approximately 14%.¹⁵ The two leading causes of kidney disease are high blood pressure and uncontrolled diabetes.¹⁵

Acute kidney injury (AKI) is a sudden (possibly over a period of days) decrease in kidney function. It is accompanied by an increase of toxins in the blood. In 2008, according to the National Kidney and Urologic Diseases Information Clearinghouse, AKI accounted for more than 23,000 hospitalizations in the United States.¹⁶ However, hospitalization rates declined significantly from 2012 to 2013, and by 10% for patients with acute kidney disease.¹⁵ More than 48,000 people with kidney disease died in 2014,¹⁷ but AKI is often reversible if promptly diagnosed and treated.

If the urine output drops to less than 500 mL per day, the condition is called **oliguria**. If urine production stops completely, the condition is called **anuria**. Whenever AKI occurs, the patient may experience generalized edema, acid buildup, and high levels of waste products in the blood. If left untreated, AKI can lead to heart failure, hypertension, and metabolic acidosis.

Chronic kidney disease is progressive and irreversible inadequate kidney function that is the result of permanent loss of nephrons. This disease develops over months or years. It is often caused by systemic diseases, such as diabetes or hypertension. In addition, chronic kidney disease can be caused by congenital disorders or prolonged pyelonephritis or can be a secondary effect of some infections, such as strep throat.

As the **nephrons** of the kidney become damaged and cease to function, scarring occurs. The tissue

FIGURE 20-4 A kidney stone.

© Jones & Bartlett Learning. Photographed by Kimberly Potvin.

begins to shrink and waste away as the scarring progresses, resulting in a loss of nephrons and renal mass. As kidney function diminishes, waste products and fluid build up in the blood. Systemic complications can develop, such as hypertension, heart failure, anemia, and electrolyte imbalances.

Patients with chronic kidney disease may exhibit a wide variety of signs and symptoms, beginning with an altered level of consciousness. In later stages, seizures and coma are possible. Additional signs and symptoms include lethargy, nausea, headaches, cramps, and signs of anemia. The patient's skin will be pale, cool, and moist, and the patient may appear jaundiced because of the buildup of wastes. A powdery accumulation of uric acid, called **uremic frost**, may also be present, especially on the face. The skin may appear bruised, and muscle twitching may be present. Patients with chronic kidney disease exhibit edema in the extremities and face because of fluid imbalances; they will also be hypotensive and have tachycardia. Pericarditis and pulmonary edema are common as well, and should be considered during auscultation of the chest.

Health expenditures for patients with chronic kidney disease are notoriously high. In 2013, Medicare spending for patients with chronic kidney disease age 65 years and older exceeded \$50 billion, representing 20% of all Medicare spending in this age group.¹⁸

End-Stage Renal Disease

If left untreated, AKI or chronic kidney disease will progress to **end-stage renal disease (ESRD)**. In a patient with ESRD, the kidneys have lost most of their ability to function, and toxic waste materials build up in the patient's blood. ESRD is fatal unless treated by dialysis or renal transplantation. In 2016, nearly 125,000 new cases of ESRD were reported in the United States, and more than 726,000 Americans were on dialysis or awaiting kidney transplants.¹⁹ Fewer than 24,000 people receive a transplant each year.²⁰

Confusion, shortness of breath, peripheral edema, bruising, chest pain, and bone pain are initial signs of ESRD. As toxins continue to accumulate, pruritus, nausea and vomiting, muscle twitching and tremors, and hallucinations may occur. Patients may also present with lethargy, headaches, cramps, and signs of anemia. The skin

is pale, cool, and moist and may appear jaundiced or bruised. Uremic frost may be present around the face. Edema of the extremities and face is apparent, and patients are hypotensive and tachycardic. Pericarditis and pulmonary edema are also common and should be evaluated during auscultation of the chest. In the late stages, seizures and coma are possible and the patient may ultimately die.

Pathophysiology of Female Reproductive Organs

Gynecologic conditions are a common cause of acute abdominal pain. Always consider that a woman with lower quadrant abdominal pain and tenderness may have a problem related to her ovaries, fallopian tubes, or uterus. Although pain may be related to the normal menstrual cycle or the release of an egg from an ovary, a common cause of an acute abdomen in women is **pelvic inflammatory disease (PID)** (infection of the fallopian tubes and the surrounding tissues of the pelvis). With PID, acute pain and tenderness in the lower part of the abdomen may be intense and accompanied by a high fever.

Between 1% and 2% of all pregnancies are ectopic.²¹ The term **ectopic pregnancy** means that a fertilized egg has come to lie in an area outside the uterus, usually in a fallopian tube. A fallopian tube is simply not large enough to support the growth of a fetus and placenta for more than about 6 to 8 weeks. When the tube ruptures, it produces massive internal hemorrhage and acute abdominal pain, generally on one side. In this situation, the acute abdomen may be associated with the onset of hypovolemic shock. Chapter 25, *Gynecologic Emergencies*, covers gynecologic emergencies in depth.

Pathophysiology of the Male Genital Tract

Epididymitis and Orchitis

One possible complication of male UTI is **epididymitis**, an infection that causes inflammation of the epididymis along the posterior border of the testis. When one or both testes become infected, this condition is called **orchitis**. With orchitis, the infection causes one or both testes to become enlarged and tender, leading to pain and swelling in

the scrotum. Swelling may occur in the groin on the affected side. The pain may increase during bowel movements. The patient will have a fever, and the urine will have a foul odor. Prehospital management of these conditions is supportive.

Priapism

Priapism, a painful, tender, persistent erection, can result from diseases such as leukemia and tumors, as well as from blunt perineal trauma, spinal cord injury, and use of cocaine, certain prescription medications, or drugs for erectile dysfunction. When this condition is present, be sure to maintain the patient's privacy and do not make assumptions about the cause of the condition. Whatever the cause, treat all patients with respect. If a spinal cord injury is suspected, ensure proper immobilization techniques.

Benign Prostate Hypertrophy

Benign prostate hypertrophy (BPH) is an age-related nonmalignant (noncancerous) enlargement of the prostate gland. It occurs in approximately 50% of men older than 60 years.²² BPH may be asymptomatic, or it may lead to difficulty starting urine flow, a slow weak urine flow once started, incomplete emptying of the bladder, increased urination at night, and urinary retention.

Testicular Masses

Testicular masses rarely require prehospital treatment. They may be painful or painless, and if painful, the pain may radiate up the spermatic cord or be localized to a specific scrotal point. Most are benign cystic masses or a varicocele—a painless mass of dilated veins posterior to the testicle. Testicular cancer usually presents as a painless solid lump on the testicle. In the United States, almost 10,000 cases are diagnosed each year, but because it can usually be treated successfully, it results in only about 440 deaths per year. The average age of diagnosis is 33 years.²³

Testicular Torsion

Testicular torsion is a twisting of the testicle on the spermatic cord, from which it is suspended. This condition is associated with the sudden onset of scrotal pain and swelling. It is a surgical emergency,

as the twisting of the vessels reduces blood flow to the testis. The torsion is usually unilateral, occurring in only one testis at a time. Torsions may occur with or without blunt trauma, a testicular lump, or blood in the semen. Patients should be carefully and promptly transported and allowed to assume the position of greatest comfort.

Pathophysiology of Other Organ Systems

The aorta lies immediately behind the peritoneum. In older people, the wall of the aorta sometimes develops weak areas that swell to form an **aneurysm** (a swelling or enlargement of a part of an artery, resulting from weakening of the arterial wall). The development of an aneurysm, unless acutely dissecting, is rarely associated with symptoms because it occurs slowly. If the aneurysm tears and ruptures, however, massive hemorrhage may occur, and the patient will present with signs of acute peritoneal irritation and hemorrhagic shock. The patient may also report severe pain radiating to the back because the peritoneum can be stripped away from the wall of the main abdominal cavity by the hemorrhage. Pain can also be associated with the pressure of blood on the back itself. In such cases, bleeding usually leads to profound shock.

A **hernia** is a protrusion of an organ or tissue through a hole or opening into a body cavity where it does not belong. Hernias can occur as a result of the following:

- A congenital defect, as around the umbilicus
- A surgical wound that has failed to heal properly
- A natural weakness in an area, such as in the groin

Hernias do not always produce a mass or lump that the patient will notice. Extreme obesity may interfere with the ability to identify the mass. At times, the mass will disappear back into the body cavity in which it belongs. In this case, the hernia is said to be reducible. If the mass cannot be pushed back within the body, it is said to be incarcerated.

Reducible hernias pose little risk to the patient; some people live with them for years. When a hernia is incarcerated, however, its contents may become seriously compressed by the surrounding tissue, eventually compromising the blood supply.

FIGURE 20-5 Common locations of abdominal hernias.

© Jones & Bartlett Learning.

This situation, called **strangulation**, is a serious medical emergency. Immediate surgery is required to remove any dead tissue and repair the hernia. In the abdomen, there are several common locations for hernias (**FIGURE 20-5**).

The following signs and symptoms indicate a serious hernia problem:

- A formerly reducible mass is no longer reducible
- Pain at the hernia site
- Tenderness when the hernia is palpated
- Red or blue skin discoloration over the hernia

Patient Assessment

Scene Size-up

As always, ensure that the scene is safe and be alert for clues to help you determine the nature of illness (NOI) or the mechanism of injury. Acute abdomen can be the result of violence, such as blunt or penetrating trauma, so always be vigilant. Chapter 32, *Abdominal and Genitourinary Injuries*, discusses traumatic injuries in detail.

Take standard precautions, using a minimum of gloves and eye protection. Consider donning a gown and covering your shoes with disposable, protective covers because there may be feces and urine on the floor and some patients may have active projectile vomiting. Examples of additional resources for a GI patient include extra gloves, mask, gowns, change of uniform, suction equipment,

extra linens, blankets, washcloths, towels, and adult and child diapers.

Determine the number of patients at the scene. Note that most calls for GI problems will not involve multiple patients. However, a call for assistance at an office building where several people are complaining about GI symptoms should lead you to suspect release of an agent. Biologic or chemical agents, for example, can cause people to have abdominal pain, nausea, vomiting, diarrhea, and other GI signs and symptoms.

Primary Survey

The first step of the primary survey is to form your general impression and determine whether a patient has an acute abdomen. The following is a checklist of common signs and symptoms of irritation or inflammation of the peritoneum:

- Local or diffuse abdominal pain or tenderness
- A quiet patient who is guarding the abdomen
- Rapid and shallow breathing
- Referred (distant) pain
- Anorexia, nausea, and vomiting
- Hematemesis (bright-red or “coffee-ground” emesis)
- Tense, often distended, abdomen
- Sudden constipation or bloody diarrhea
- Dark, tarry stool (melena)
- Painful or frequent urination
- Discolored urine accompanied by a strong odor
- Tachycardia
- Hypotension
- Fever

Patients who are experiencing renal or genital problems may exhibit many of the same symptoms as a patient with other abdominal problems—nausea and vomiting, constipation or diarrhea, flank pain, and abdominal pain.

In forming your general impression, closely examine the location where the patient is found, because it can provide hints about what happened. Was the patient walking to the bathroom when they passed out? Has the patient been sick for several days and camped out on the couch? Was the patient at work when a sudden bout of pain came on?

A patient with urologic or renal problems may exhibit extremes of activity. Is the patient constantly

changing positions to find a comfortable position (the kidney stone dance)? Or is the patient sitting very still, with the knees drawn to the chest? Is the abdomen distended or rigid?

In some situations, patients are comfortable only when lying in a specific position, which tends to relax muscles adjacent to the inflamed organ and thus lessen the pain. Therefore, the position of the patient may provide you with an important clue. For example, a patient with appendicitis may draw up the right knee, whereas a patient with pancreatitis may lie curled up on one side.

One aspect of the general impression that is different for GI patients is odor. What is the smell of the room or location of the patient? There are few EMS calls that rise to the level of noxious odor as those that involve upper GI bleeding. The foul-smelling stool that accompanies these calls can make even an experienced AEMT nauseated. When dealing with these strong odors, the key is to hold your ground. The sense of smell is the most acute for approximately 1 minute, after which the intensity of an odor decreases when the olfactory nerve tires of sending the same signal. If you are faced with a strong odor on a call, stay in the environment. After 2 to 5 minutes, the smell may be barely noticeable.

It is not critical for you to determine the cause of acute abdomen; rather, your priority is to recognize potential causes and provide the correct supportive care.

Special Populations

Use a hands-off assessment to establish a general impression when dealing with pediatric patients. Until a rapport is established, touching a child may cause anxiety and distress, which can alter assessment findings.

Evaluate the patient's airway, breathing, circulation, disability, and exposure (ABCDEs), and immediately care for any life threats. Airway patency becomes a pertinent concern with a GI patient. A patient who is vomiting has a greater chance to aspirate. In patients who are awake and responsive, positioning is key to maintaining a patent airway. In patients who have an altered mental status, open the airway using the appropriate maneuvers. Inspect the airway closely for foreign bodies. Remove or suction any obstructions that are found. While evaluating the airway, notice any unusual odors emanating from the mouth. Patients who have

YOU are the Provider

Part 3

You explain your concerns to the patient, and he agrees to allow you to transport him to the emergency department (ED), even though he says, "All I need is to get my dialysis." As you place the patient on the stretcher and secure him, he begins to become increasingly short of breath and starts to vomit. Your partner provides the patient with 100% oxygen via a nonbreathing mask and gives him an emesis bag while you attempt to insert an IV line.

Recording Time: 10 Minutes

Respirations	36 breaths/min, crackles bilaterally
Pulse	Strong and regular, 140 beats/min
Skin	Warm and dry
Blood pressure	226/108 mm Hg
Oxygen saturation (SpO₂)	94% on 100% oxygen
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Does this patient need IV access?
- What are your treatment options for this patient?
- What could be a cause of this patient's shortness of breath?

extremely advanced bowel obstructions can have feculent breath, smelling of stool.

GI problems rarely affect breathing directly. If a breathing problem is encountered, it typically stems from a severe complication. Ensure that the airway is clear. In particular, if the patient has aspirated a substance, it can affect the ability to oxygenate and ventilate. Also, as a result of the abdominal pain, the patient may show shallow or inadequate respirations because deep breaths often intensify the pain.

The assessment of the circulatory system is essential in understanding how the GI issue is affecting the body. The patient's pulse rate and quality, as well as skin condition, may indicate shock. Check the pulses in both arms because a difference in pulse strength may indicate an aortic dissection. Expose the patient and assess for major bleeding.

Words of Wisdom

When measuring the blood pressure in a dialysis patient, always use the arm that does not have the shunt. Placing the blood pressure cuff over the shunt or fistula may damage it or cause a clot to form. Some patients will have multiple shunts. Rather than remove those that are no longer working, they are left in place. Always ask the patient which arm to use when more than one shunt is present.

Many GI diseases involve pain and/or hemorrhage. Shock may be caused by hypovolemia or may be the result of a severe infection (sepsis). If evidence of shock (inadequate perfusion) is present, interventions should include high-flow oxygen, keeping the patient warm, and placing the patient in the position dictated by local protocol for shock patients. Ensure that you provide prompt treatment for life threats, and do not delay in providing transport.

Orthostatic vital signs, obtained by assessing vital signs in two different patient positions, will help you determine the extent of bleeding that has occurred, if any. First, have the patient assume a position of comfort, usually seated or lying down. Obtain an accurate blood pressure and heart rate. Next, have the patient change positions (that is, have the patient stand or sit up). Use caution, because the patient may lose consciousness with a positional change. Wait a minute or two, and then repeat the blood pressure and heart rate

measurements. Normally, there should be little change in the blood pressure or heart rate with such a positional change. When a patient has a significant loss of fluid within the vascular space, however, there may be a 10-beat increase in the heart rate and/or a 10-mm Hg drop in blood pressure. A decrease in a patient's blood pressure while sitting up from a lying position or when standing up from a sitting position is called **orthostatic hypotension**.

When you examine a patient with a GI problem for gross bleeding, it is not unusual to find large amounts of blood. Take note of the amount of blood lost, focusing on being accurate. The emotional effects of seeing large amounts of blood could lead people to overestimate the volume lost. The amount of blood in a toilet is particularly difficult to estimate owing to dilution. To practice volume estimation, measure the amount of water in a glass, and then spill it on a carpet; note the size of the puddle. Spill another volume of water on a hard surface such as a tile floor; again, note the size of the puddle.

When making your transport decision, integrate the information obtained in the primary survey. If the patient has positive orthostatic vital signs (that is, serial vital signs change with a change in position), thoughtfully consider how the patient will be moved. Can the patient sit up in a stair chair, or could that result in a loss of consciousness? Is the patient's condition critical, requiring urgent transfer?

Patients who have airway, breathing, or circulation problems, including problems with pulse and perfusion, and those with suspected internal bleeding require rapid transport. Included in the group to package quickly and transport rapidly are patients who have a poor general impression, especially pediatric and geriatric patients. Pale, cool, diaphoretic skin; tachycardia; hypotension; and altered level of consciousness are all signs of significant illness.

Ensure that the ride during transport is as gentle as possible for the patient. Drive smoothly and steadily. Rapid driving can result in increased vehicle movement, potentially aggravating and possibly worsening the patient's abdominal pain.

Words of Wisdom

An acute abdomen is characterized by abdominal pain and tenderness.

History Taking

Pain is often a finding of importance in patients with GI problems because it can indicate trauma, hemorrhage, infection, or obstruction. As with the primary survey, use OPQRST-I (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, and Interventions) to elaborate on the chief complaint. **TABLE 20-4** describes the types of pain that may be experienced with an abdominal problem.

In patients with a urologic problem, the patient history and physical examination will provide the information needed to successfully manage the patient. Determining that the pain actually started in the flank and not in its present location of the lower right quadrant could mean the difference between a correct field diagnosis of a kidney stone and an incorrect field diagnosis of appendicitis. Similarly, determining that the patient has a history of diabetes and hypertension along with signs of uremia can help confirm your impression of chronic kidney disease.

The SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history will help elicit the relevant current and past medical history. It may not affect the interventions

you perform, but it will help provide needed information for the physician in the ED to aid in determining the cause of the acute abdomen.

When asking patients about their complaints, you often need to discuss subjects that are not commonly described with everyday language. It is important that you and your patient have a common frame of reference. For example, one person's "diarrhea" may be another person's "soft stool."

Ask the following questions specific to the signs and symptoms of a GI or urologic emergency:

- **Nausea and vomiting.** Do you feel nauseated? Have you vomited? How many times? In which period of time? Was there red blood? Did it look like coffee grounds?
- **Changes in bowel habits.** Has there been any change in your bowel habits? Have you been constipated? Did the stool look dark and tarry? Have you had diarrhea? How many bowel movements have occurred, and over what period of time? Was there any red blood in it?
- **Urination.** Have you been urinating more or less often than usual? Is there pain when you urinate? Is the color of the urine dark or unusual? Is there an unusual odor?
- **Weight loss.** Have you lost weight recently? How many pounds?

TABLE 20-4 Types of Abdominal Pain

Abdominal Pain Type	Origin	Description	Cause
Visceral discomfort	Hollow organs	Difficult to localize Described as burning, cramping, gnawing, or aching Usually felt superficially	Organ contracts too forcefully or is distended (stretched)
Parietal pain/rebound pain	Peritoneum	Steady, achy pain Easier to localize than visceral Increases with movement	Inflammation of the peritoneum (caused by bleeding or infection)
Somatic pain	Peripheral nerve tracts	Localized pain, usually felt deeply	Irritation of or injury to tissue, causing activation of peripheral nerve tracts
Referred pain	Peripheral nerve tracts	Pain originating in the abdomen and causing the perception of pain in distant locations Usually occurs after initial visceral, parietal, or somatic pain	Similar paths for the peripheral nerves of the abdomen and the distant location

- **Belching or flatulence.** Have you experienced belching or flatulence? For how long?
- **Pain.** What does the pain feel like? How long have you had this pain? Is the pain constant or intermittent?
- **Concurrent chest pain.** If the patient reports chest pain, use OPQRST-I.
- **Other.** Ask about any other signs or symptoms related to this complaint, such as “Are there any changes you have noted recently that may be contributing to your pain?”

Continue with the SAMPLE history. Has the patient experienced this kind of abdominal pain before? If the patient is female and of childbearing age, identify the date of her last menstrual period. This will help determine if the patient could possibly be pregnant or raise the suspicion of an ectopic pregnancy. Has the patient undergone any surgery or recent hospitalizations?

It is important to determine whether the patient has ingested any substance that could be causing the acute abdomen. If eating causes pain, discomfort, vomiting, or diarrhea, the patient will

eat less often or stop eating. Do not give the patient anything by mouth, as food or fluid may aggravate many of the symptoms. Also, the presence of food in the stomach increases the risk of aspiration, especially if the patient needs emergency surgery.

Finally, determine the events that led up to the patient's present illness. It is important to determine whether this is a medical emergency or related to trauma.

Secondary Assessment

Information gathered in the history-taking portion of the patient assessment may be used to focus your physical examination of the abdomen. A normal abdomen is soft and not tender. In contrast, an acute abdomen is characterized by pain and tenderness. The pain may be sharply localized or diffuse and will vary in its severity. Localized pain gives a clue to the problem organ or area causing it. Tenderness may be minimal or so great that the patient will not allow you to touch the abdomen. In some instances, the muscles of the abdominal wall become rigid in an involuntary effort to protect the abdomen from further irritation. This boardlike muscle spasm, called **guarding**, can be seen with major problems such as a perforated ulcer or pancreatitis. You may also note the presence of **ascites**, a collection of edema in the abdomen typically caused by liver failure.

Assessment Pearls

- Be alert for initial signs of internal bleeding: anxiety, slight increases in heart rate and respirations, and skin changes.
- Watch for patient reactions during assessment: grimacing, guarding, etc.
- Look before you touch! Note any discoloration, traumatic marking, or swelling/distention prior to palpating.
- *Gently* palpate, paying particular attention to any masses. If a mass is detected, lightly place your hand over it to feel for any pulsations.
- Abdominal pain is often diffuse, making the origin difficult to detect. Do not discount severity of the patient's condition if the source of the pain cannot be pinpointed.
- Place the patient in a position of comfort, maintain the airway and oxygenation, keep warm, and provide rapid transport. Gain IV access en route.
- Reassess, reassess, reassess! It is imperative to recognize subtle changes that may lead to a rapid decline in patient condition.

Words of Wisdom

When you are palpating the abdomen, always begin on the side farthest from the site of pain.

Words of Wisdom

An acute abdomen may indicate peritonitis, in which generalized signs can make it challenging to determine exactly where the problem lies, even for physicians. Knowing the abdominal assessment steps well and recording your findings in detail are important early components of the process that leads to diagnosis.

A patient with peritonitis usually has abdominal pain, even when lying quietly. The patient may have difficulty breathing and may take rapid, shallow breaths because of the pain. Usually, you will find tenderness on palpation of the abdomen or when the patient moves. The degree of pain and tenderness is usually related directly to the severity of peritoneal inflammation.

Use the following steps to assess the abdomen:

1. Explain to the patient what you are going to do in terms of assessing the abdomen.
2. Place the patient in a supine position with the legs drawn up and flexed at the knees to relax the abdominal muscles. If trauma is involved, the patient should remain supine and stabilized. Determine whether the patient is restless or quiet and whether motion causes pain.
3. Expose the abdomen and visually assess it. Does the abdomen appear distended (enlarged)? Do you see any pulsating masses (indicates an aortic aneurysm)? Is there bruising to the abdominal wall? Are there any surgical scars?
4. Ask the patient where the pain is most intense. Palpate in a clockwise direction beginning with the quadrant *farthest* from the one the patient indicates is tender or painful; end with the quadrant the patient indicates is tender or painful. If the most painful area is palpated first, the patient may guard against further examination, making your assessment more difficult and less reliable.
5. Be very gentle when palpating the abdomen. Occasionally, an organ within the abdomen will be enlarged and very fragile, such that rough palpation could cause further damage. If you see a pulsating mass, do not touch it; doing so could cause the aorta to rupture.
6. Palpate the four quadrants of the abdomen gently to determine whether each quadrant is tense (guarded) or soft when palpated (**FIGURE 20-6**).
7. Note whether the pain is localized to a particular quadrant or diffuse (widespread).
8. Palpate and wait for the patient to respond, looking for a facial grimace or a verbal “ouch.” Do not ask the patient, “Does it hurt here?” as you palpate.

FIGURE 20-6 Check for tenderness or rigidity by gently palpating the abdomen.

© Jones & Bartlett Learning.

9. Determine whether the patient exhibits rebound tenderness (may be tender when direct pressure is applied, but very painful when pressure is released). This is an indicator of peritonitis.
10. Determine whether the patient can relax the abdominal wall on command. Guarding or rigidity may be present, which can indicate peritoneal irritation.

Street Smarts

When assessing for rebound tenderness, it is important to describe to the patient what you are going to do prior to touching. Explain by stating, “I am going to press down on your abdomen and then hold it for a few seconds before I release it. I need you to tell me whether it hurts more when I press down or when I let go.”

Findings of a high respiratory rate with a normal pulse rate and blood pressure may indicate the patient is unable to ventilate properly because deep breathing causes pain. A high respiratory rate and pulse rate with signs of shock, such as pallor and diaphoresis (profuse sweating), may indicate septic or hypovolemic shock.

Use pulse oximetry and noninvasive blood pressure devices when these monitoring devices are available. It is recommended that you always obtain the patient's first blood pressure reading manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

Special Populations

Abdominal injuries are the third leading cause of trauma-related deaths in children (after head and chest injuries).²⁴ In pediatric patients, the intra-abdominal organs are relatively large, making them vulnerable to blunt trauma. For example, the abdomen in an infant or toddler often seems protuberant because of the large liver. The liver and spleen extend below the rib cage in young children and, therefore, do not have as much bony protection as they do in an adult. These organs have a rich blood supply, so injuries to them can result in large blood losses. The kidneys are also more vulnerable to injury in children because they are more mobile and less well supported than in adults. Finally, the duodenum and pancreas are likely to be damaged in handlebar injuries.

Owing to their smaller fluid volume, children dehydrate quickly from vomiting. Abdominal pain in children often is the result of constipation; however, appendicitis is also another frequent cause of abdominal pain. Remember to assess for GI bleeding as well. Management of pediatric patients with abdominal complaints is the same as that for adults. Use a hands-off approach to get a general impression of the patient before touching to adequately assess any signs of distress.

Reassessment

Because it is often difficult to determine the cause of an acute abdominal emergency, it is extremely important to reassess the patient frequently to determine whether the patient's condition has changed. Remember, the condition of a patient with an acute abdomen can change rapidly from stable to unstable.

Vital signs must be reassessed and compared with the patient's baseline vital signs. If anything changes en route to the hospital, manage the problem and document any changes or additional treatment.

Reassess the patient and then ask and answer the following questions (where appropriate):

- Has the patient's level of consciousness changed?
- Has the patient become more anxious?
- Has the appearance of the skin changed?
- Has the pain gotten better or worse?

- Has bleeding increased or decreased?
- Is the current treatment improving the patient's condition?
- Has an already-identified problem gotten better or worse?
- What is the nature of any newly identified problems?

If the patient has GI bleeding, continue to assess for signs of shock. Before giving additional fluid boluses, listen to the patient's lung sounds to determine whether acute pulmonary edema is developing. If the patient wants to lie on one side, try to make that possible. Be sure that you can observe and maintain the patient's airway because vomiting is common in patients with GI conditions.

If the patient's condition is unstable, call for paramedic backup. If transport time is extended and rapid transport is needed, consider air medical transport if available.

Patients with urologic emergencies, especially patients with signs and symptoms of renal failure, also need reassessment. The electrolyte imbalances caused by the buildup of toxins can cause major, rapid changes in the functioning of the body's organs. Serial vital signs should be obtained and documented on the prehospital care report—at least every 5 minutes in cases of possible renal failure. Note any trends in the vital signs and level of consciousness, because they can be indicators of disease progression. Patients with possible urologic disease should not be given anything by mouth because this may induce vomiting or complicate surgical procedures.

Emergency Medical Care

The signs and symptoms of an acute abdomen signal a serious medical or surgical emergency. Ensure that you provide prompt, gentle transport for the patient; do not delay transport. Carry out the following steps as quickly as possible before transport:

1. Do not attempt to diagnose the cause of the acute abdomen.
2. Clear and maintain the airway.
3. Anticipate vomiting. Place the patient in the recovery position or position of comfort. Most patients feel better in a lateral recumbent position with the knees pulled in toward the chest.

4. Administer 100% supplemental oxygen, and be prepared to assist ventilation if the patient has a reduced tidal volume (shallow breathing).
5. Do not give the patient anything by mouth. Food or fluid will merely aggravate many of the symptoms, because intestinal paralysis will prevent it from passing out of the stomach. In addition, the stomach must be empty if surgery is to be performed, meaning surgery will have to be delayed or emergent surgery will be done with increased risk of aspiration.
6. Document all pertinent information. Use the OPQRST-I mnemonic. Note the presence of abdominal tenderness, distention, or guarding.
7. Anticipate the development of hypovolemic shock. Monitor blood pressure. Treat the patient for shock when it is evident. Place the patient in the position dictated by local protocol for shock patients.
8. Establish IV access, and give a 20-mL/kg bolus of an isotonic crystalloid if the patient presents with signs of hypovolemia. Otherwise, administer fluids at a to-keep-open rate. If kidney function is present, administer a bolus of fluid to the patient with a UTI and to the patient with a kidney stone. The fluid will rehydrate the patient, and an increased volume of urine will help flush any infection from the system. For a patient with kidney stones, the increased urine formation will help move the stone through the system.
9. Make the patient as comfortable as possible for transport. Patients are usually more comfortable with their legs pulled up toward the abdomen, because this position takes the pressure off the abdominal wall and diminishes pain. Conserve body heat with blankets, as needed. Provide gentle but rapid transport and constant psychological support.
10. Monitor vital signs; these may change quickly.
11. Consider calling for additional paramedic backup if the patient's condition shows any signs of instability.

Remember that in female patients with PID, acute pain and tenderness in the lower part of the abdomen may be intense and accompanied by a high fever. If you suspect PID, promptly transport the patient to the ED for treatment.

The combination of acute abdominal pain and hypovolemic shock mandates immediate transport to the hospital. Consider an ectopic pregnancy in any female of childbearing age who presents with acute abdominal distress, especially in the presence of hypotension.

Pneumonia, especially in the lower parts of the lung, may cause both ileal and abdominal pain. In this case, the problem lies in an adjacent body cavity, but the intense inflammatory response can affect the abdomen. Treat and transport this patient as you would any patient with abdominal pain.

The association of acute abdominal signs and symptoms with shock could also signify an aneurysm and requires prompt transportation. Because this is a fragile situation with a large, leaking artery, avoid unnecessary and vigorous palpation of the abdomen. Handle the patient gently during transport. Administer fluid only if the patient is hypotensive *and* symptomatic. Increasing blood pressure could cause rupture of an aneurysm.

Any signs and symptoms of a hernia in a patient with acute abdominal pain are cause for prompt transport to the ED as the pain could be caused by an incarceration or strangulation of the hernia.

Finally, AKI and chronic kidney disease can lead to life-threatening emergencies. Support of the ABCs is imperative. Be alert for the possibility of hypotension or pulmonary edema. Because of possible toxic buildup and electrolyte problems, medications to regulate acidosis and electrolyte imbalance and fluids for volume regulation may be required. Emergency transport and supportive care are often preferred instead of aggressive management in these patients.

Renal Dialysis

The only definitive treatment other than transplantation in cases of ESRD is **renal dialysis**. In this process, the patient's blood is filtered and cleansed of the toxins and then returned to the body. The treatment eliminates waste, normalizes the blood chemistry, and reduces excess fluid. Renal dialysis and problems associated with it may prompt calls for prehospital care.

Two types of dialysis may be performed—peritoneal dialysis and hemodialysis. In peritoneal dialysis, large amounts of specifically formulated

dialysis fluid are infused into (and back out of) the abdominal cavity. This fluid stays in the cavity for 1 to 2 hours, allowing equilibrium to occur. Peritoneal dialysis is very effective but carries a high risk of peritonitis; consequently, aseptic technique is essential. With proper training, however, peritoneal dialysis can be performed in the home.

In hemodialysis, the patient's blood circulates through a dialysis machine that functions in much the same way as the normal kidneys. Most patients undergoing long-term hemodialysis have some sort of **shunt**; that is, a surgically created connection between a vein and an artery that is usually located in the forearm or upper arm. The patient is connected to the dialysis machine through this shunt, which allows blood to flow from the body into the dialysis machine and back to the body. Some patients have an **internal shunt** (an arteriovenous [AV] fistula), which is an artificial connection between a vein and an artery that is usually located in the forearm or upper arm (**FIGURE 20-7**).

In patients with a life-threatening emergency, the internal shunt may be used for IV access. In all other instances, an alternative IV site should be selected. AV shunts should not be used for routine blood draws.

You will most likely see a dialysis machine only if your service transports patients to and from

FIGURE 20-7 With an arteriovenous fistula, a bulge is created beneath the skin by arterial pressure at the site where the artery and the vein have been directly connected.

© Jones & Bartlett Learning.

dialysis centers. If there is a dialysis machine in a private residence, treatments will most likely be performed by a trained dialysis technician and only rarely by the patient or family members.

Patients requiring long-term dialysis usually undergo this process every 2 or 3 days for a period of 3 to 5 hours. Many receive dialysis in the hospital or in community dialysis facilities, but a significant number have home dialysis units. Patients undergoing dialysis at home usually have extensive training in the procedures, and often someone else in the home has also been trained. If a problem with

YOU are the Provider

Part 4

Venous access is difficult in this patient, but you are able to place a 22-gauge saline lock in the patient's right hand to be used as a medication route. You radio medical control, advising of the patient's condition, and are informed to withhold any IV fluid in this patient. You advise medical control that you have an approximately 7-minute estimated time of arrival.

Recording Time: 15 Minutes

Respirations	36 breaths/min; crackles bilaterally
Pulse	Strong and regular; 142 beats/min
Skin	Warm and dry
Blood pressure	210/102 mm Hg
Oxygen saturation (Spo₂)	95% on 100% oxygen

You continue monitoring the patient en route to the hospital. On arrival, you give your report to the ED nurse and complete your patient care report while your partner readies the ambulance for your next call.

9. Why did the medical control physician order that no IV fluid be administered to this patient?

the machine occurs, the patient may know a lot more about it than you do, so always ask what the patient has done before your arrival!

Although patients undergoing chronic dialysis can experience the same spectrum of illnesses and injuries as other patients, they are particularly vulnerable to certain conditions, either because of the dialysis itself or because of the underlying renal failure. Conditions associated with dialysis may result from accidental disconnection from the machine, malfunction of the machine, or rapid shifts in fluids and electrolytes. In addition, many adverse effects and complications can occur with dialysis; these are listed in **TABLE 20-5**.

A sudden drop in blood pressure is not uncommon during or immediately after dialysis, but it can lead to cardiac arrest if not promptly detected and treated. The patient may feel light-headed or become confused, and often yawns more than usual. Because dialysis alters the blood's chemistry, an electrolyte imbalance may develop. For this reason, you should consider the possibility of cardiac dysrhythmias and the need for advanced life support backup. Shock secondary to bleeding is also possible from any number of causes. Patients with chronic kidney disease, for example, are highly susceptible to duodenal ulcers; bleeding from those ulcers is not unusual. Bleeding may also occur from the dialysis cannula.

Also, if a patient misses a dialysis treatment, they may experience weakness, pulmonary edema, or excesses of electrolytes. If your call involves a patient on dialysis, start with the ABCDEs and manage

Words of Wisdom

Bleeding from a fistula that cannot be controlled with direct pressure after the dialysis needle is removed may be difficult to manage. If bleeding is brisk, apply firm pressure with the fingertips of one hand over the bleeding site while using the other hand to apply pressure proximal to the bleeding area for 15 to 30 minutes. Massive bleeding that cannot be controlled in this manner may require the application of a tourniquet.

them as necessary. Provide high-flow oxygen if indicated and manage any bleeding from the access site. Position the patient sitting up in cases of pulmonary edema or supine if the patient is in shock, and transport promptly.

When you find a shunt leaking during the dialysis cycle, see if you can tighten the connection. If it has become disconnected at the vein, clamp the cannula and disconnect the patient from the machine. In a suicide attempt, the patient may open up the cannula and allow the blood to flow out, called exsanguination. Keep in mind that patients receiving dialysis have often endured numerous medical interventions to simply survive. If you encounter this situation, immediately clamp off the cannula and apply direct pressure.

Some dialysis patients also have urinary catheters. The catheter is placed in the bladder so the urine can run into a bag. These catheters can often be a source of infection. The patient may report fever and general malaise (illness) in addition to any symptoms specific to kidney failure. Leave the device in place. Treat any signs and symptoms and transport the patient for further evaluation.

During transport, unless there is a life-threatening event, make all attempts to deliver the patient to a hospital with dialysis capability.

Disequilibrium Syndrome

Dialysis rapidly lowers the concentration of urea in the blood, whereas the concentration of solutes in the cerebrospinal fluid (CSF) remains high. Water moves by osmosis from a solution of lower concentration into a solution of higher concentration. With dialysis, water initially shifts from the bloodstream into the CSF, thereby mildly increasing intracranial pressure. In such a circumstance, the patient may experience **disequilibrium syndrome**, a

condition characterized by nausea, vomiting, headache, and confusion. After a few hours, the fluid will re-equilibrate between the blood and CSF, and the patient's symptoms may improve on their own.

Words of Wisdom

In the field, it may be impossible to distinguish between disequilibrium syndrome and subdural hematoma, to which dialysis patients are particularly vulnerable. In such a case, transport the patient to the hospital immediately for a full neurologic evaluation.

Air Embolism

If any of the fittings and connections in the dialysis system are loose, air may enter the system, producing an **air embolism** in the patient. Symptoms of an air embolism include sudden dyspnea, hypotension, and cyanosis. If you suspect an air embolism, disconnect the patient from the dialysis machine. Per the Advanced Renal Education program, flat supine position for such a patient may be better than the traditionally advocated left lateral (Duran) and Trendelenburg position (position in which the body is supine with the head lower than the feet).²⁵ Transport the patient immediately.

YOU are the Provider SUMMARY

1. What are some potential causes of altered mental status in a patient receiving dialysis?

Common causes of altered mental status in a patient receiving dialysis are the same causes of altered mental status in patients who do not receive dialysis. However, when the dialysis patient has missed a dialysis appointment or has gone longer than normal in between treatments, the patient is particularly susceptible to an electrolyte imbalance that is the result of the buildup of toxins in the bloodstream.

2. On the basis of the information provided, which type of dialysis does this patient receive?

The two types of dialysis are peritoneal dialysis and hemodialysis. In peritoneal dialysis, large amounts of specially formulated dialysis fluid are infused into (and back out of) the abdominal cavity. In hemodialysis, the patient's blood circulates through a dialysis machine that functions in much the same way as the normal kidneys. The patient is connected to the dialysis machine through a shunt, which allows blood to flow from the body into the dialysis machine and back to the body. This type of dialysis is almost exclusively found in dialysis centers. Hemodialysis is the type of dialysis this patient is receiving.

3. What is anuria?

Anuria is the complete cessation of urine production. If the urine output drops to less than 500 mL per day, the condition is called oliguria.

4. The patient seems to be answering all questions appropriately, but more slowly than what is reported to be normal. Should you approach the dialysis staff and request that he undergo dialysis in an attempt to help improve his mental status?

This treatment would be a possibility, but it would probably not be recommended. Dialysis needs to be

performed on a routine basis, and missing or delaying a treatment may have a major effect on the patient's well-being. The patient's slowness to respond to questions, coupled with the patient's statement that this condition is not normal for him, warrants a trip to the ED.

5. You note a "lump" in the patient's left forearm. What is this lump, and why is it important for you to note?

Some patients receiving dialysis have a shunt, which is a surgically created access port usually located in the forearm or upper arm. It is important for AEMTs to recognize the presence and location of this shunt because the arm without the shunt should be used, if possible, for blood pressure measurements and IV lines.

6. Does this patient need IV access?

This patient could benefit from IV access for multiple reasons. First, he has an altered mental status and shortness of breath. Those two conditions alone are reason enough to insert an IV line, not only for possible fluid administration, but also as a medication route. Because this patient has a chronic medical condition, he may have poor venous access. In such a case, it would be prudent to establish IV access in this patient while he is still in somewhat stable condition, before he starts to decompensate, when it will be more difficult to establish access.

7. What are your treatment options for this patient?

There are multiple options for treatment in this patient, and some are better than others. This patient presents with crackles bilaterally. Call for paramedic backup to administer medications or to administer continuous positive airway pressure, which may also be beneficial in clearing up the crackles. Regardless

YOU are the Provider SUMMARY *continued*

of the treatment path you decide to take, 100% oxygen is indicated, but careful attention must be given to the patient in case of more emesis.

8. What could be a cause of this patient's shortness of breath?

Because there is a longer time frame between dialysis treatments over the weekend (2 days) as opposed to the more frequent treatments during the week, this patient's shortness of breath is probably caused by an accumulation of fluid inside of the

body, exacerbated by the possibility of increased salt, sugar, and fluid intake during the birthday party.

9. Why did the medical control physician order that no IV fluid be administered to this patient?

Owing to this patient's anuric state, hypertension, presence of crackles, and unknown time until his next dialysis treatment, the medical control physician most likely thought that the patient was already fluid overloaded.

Narrative

EMS called to above location for a male patient to be transported to the ED. On arrival, met by dialysis clinic staff, who stated patient regularly receives dialysis on M, W, and F. Today patient came in for regularly scheduled treatment, but staff found him slow to answer questions and mildly short of breath. Patient is AO × 3 but is slow to answer questions. Both patient and staff state this is abnormal for him. Patient has mild dyspnea, with crackles bilaterally. Patient was assisted onto stretcher and secured. While preparing patient for transport, patient vomited × 1. Administered oxygen @ 15 L/min, via nonrebreathing mask. Transported nonemergency to Upson Regional Hospital. 22-gauge saline lock established in right hand. No fluid administered per medical control. Patient remains moderately short of breath. Report called to ED with condition and ETA. On arrival at ED, report given to nurse without incident.

End of report

Prep Kit

Ready for Review

- The GI system is also known as the digestive tract. Its main function is to absorb the products of digestion to fuel the cells within the body.
- The digestive process begins with saliva to lubricate food. Once food is swallowed, it moves through the esophagus via rhythmic contractions called peristalsis.
- Veins intertwine around the esophagus and join to form the portal vein, which transports blood from the GI tract to the liver. If blood flow through the liver slows, blood may back up throughout the entire GI system.
- The stomach secretes hydrochloric acid to help break down food. The material then moves into the small intestine.
- The small intestine is divided into the duodenum, the jejunum, and the ileum. The small intestine produces enzymes that turn digested food into substances that can be moved into the bloodstream.
- The duodenum is where the active stage of absorption begins. The pancreas and liver secrete enzymes and bile, respectively, which ultimately assist digestion in the small intestine.
- The liver also converts glycogen into glucose, the essential and only fuel source for brain cells. The liver also detoxifies drugs, completes the breakdown of dead red and white blood cells, and stores vitamins and minerals.
- The large intestine, or colon, is the next step in the digestive process. The primary role of the large intestine is to complete the reabsorption of water. This process helps solidify the digested material into a formed stool. The colon is also the site of digestion by bacteria, which helps to finish the breakdown of chyme.
- The genitourinary system includes the kidneys, urinary bladder, ureters, urethra, male and female reproductive organs, and specific structures within the kidneys.
- Any condition that allows pus, blood, feces, urine, gastric juice, intestinal contents, bile, pancreatic juice, amniotic fluid, or other foreign material to lie within or adjacent to the peritoneum in the abdominal cavity can cause peritonitis and, therefore, an acute abdomen.
- Acute abdomen can be caused by GI or renal sources: diverticulitis, cholecystitis, appendicitis, perforated gastric ulcer, aortic aneurysm, hernia, cystitis, kidney infection, kidney stone, pancreatitis, and UTI. In women, additional causes include ectopic pregnancy and pelvic inflammation.
- Peritonitis typically causes ileus (paralysis of peristalsis) and ultimately abdominal distention. It is almost always associated with nausea and vomiting and can lead to hypovolemic shock.
- GI hemorrhage can be acute, which may be shorter term in duration and more severe, or chronic, which may be of longer duration and less severe. All complaints of bleeding should be considered serious. Sources of GI hemorrhage may include esophagitis, peptic ulcer disease, Mallory-Weiss tears, esophageal varices, gastroesophageal reflux disease, and hemorrhoids.
- Nonhemorrhagic conditions affecting the GI system include gallstones, pancreatitis, appendicitis, gastroenteritis, and diverticulitis. All of these conditions are characterized by abdominal pain, which is often localized to a particular quadrant depending on the source.
- Chronic inflammatory conditions of the colon include ulcerative colitis, irritable bowel syndrome, and Crohn disease. These conditions are all characterized by changes in bowel habits and can range from mild to severe in their signs and symptoms.
- Symptoms of UTI include painful urination, frequent urges to urinate, difficulty urinating, and possibly referred pain to the shoulder or neck. The urine may have a foul odor and be cloudy.
- Kidney stones result from crystallization of an excess of insoluble salts or uric acid in the urine. Symptoms include severe pain in the flank that may migrate forward to the groin.
- AKI is a sudden decrease in kidney filtration, resulting in a release of toxins into the blood. Chronic kidney disease is progressive and irreversible inadequate kidney function. In

end-stage renal disease, the kidneys have lost all ability to function, and toxic waste materials build up in the patient's blood; this condition is fatal unless treated by dialysis or renal transplant.

- Gynecologic problems are a common cause of acute abdominal pain. Always consider that a woman with lower abdominal pain and tenderness may have a problem related to her ovaries, fallopian tubes, or uterus.
- Conditions related to the male genital tract include epididymitis and orchitis (which stem from infection of the epididymis and testes, respectively), priapism (painful tender, persistent erection), BPH, testicular masses, and testicular torsion.
- Abdominal pain may stem from other organ systems. If an abdominal aortic aneurysm ruptures, massive hemorrhage may occur and signs of acute peritoneal irritation will present. A hernia (protrusion of an organ or tissue through a hole in the body) may eventually compromise blood supply to the tissue or organ protruding through, causing a serious emergency.
- GI complaints often involve body substances. Take extra gloves, masks, gowns, and other protective equipment and supplies with you to the scene.
- In a patient with an acute abdomen, the first priorities are to assess airway, breathing, and circulation, and then apply oxygen. Assist ventilation if the patient is breathing inadequately.
- When taking the patient's history, ask when the symptoms began, how they have changed, where the pain is located (be precise), and how it feels. Also ask if there has been vomiting or diarrhea.
- Airway concerns may arise with a patient who is vomiting. Open the airway using the appropriate maneuvers, and closely inspect it for foreign bodies. Remove or suction any obstructions that are found.
- Abnormal abdominal assessment findings include excessive nausea/vomiting or hematemesis; changes in bowel habits/stool; painful or frequent urination that is discolored or has a strong odor; weight loss; belching/flatulence; concurrent chest pain; and abdominal pain, tenderness, guarding, or distention.
- Pain is commonly located directly over the inflamed area of the peritoneum, or it may be referred to another part of the body.
- A healthy or normal abdomen should be soft and not tender. The pain in an acute abdomen may be sharply localized or diffuse, and will vary in severity. Localized pain gives a clue to the problem organ or area causing it. The abdominal muscles may have become rigid, called guarding.
- In a patient with a GI condition, take vital signs, and gently palpate the abdomen. If the abdomen is tender, the patient needs to be transported urgently.
- Note the degree of abdominal distention; it can provide clues to the severity of the patient's condition.
- Patients with acute abdomen may be comfortable only when lying in one particular position—for example, curled up on one side or with the right knee drawn up. Note the patient's position.
- Do not give the patient with an acute abdomen anything by mouth; establish intravenous access; consult with medical control to administer pain medication, and transport the patient promptly but gently.
- Renal dialysis is a procedure for removing toxic wastes and excess fluids from the blood. Patients receiving hemodialysis usually have a shunt through which they are connected to the dialysis machine. They are vulnerable to problems such as hypotension, potassium imbalance, disequilibrium syndrome, and air embolism.

Vital Vocabulary

acute abdomen A condition of sudden onset of pain within the abdomen, usually indicating peritonitis; demands immediate medical or surgical treatment.

acute kidney injury (AKI) A sudden decrease in filtration through the glomeruli of the kidneys.

air embolism The presence of air in the venous circulation, which forms a gas bubble that can

block the outflow of blood from the right ventricle to the lung; can lead to cardiac arrest, shock, or other life-threatening complications.

aneurysm A swelling or enlargement of a part of an artery, resulting from weakening of the arterial wall.

anuria A complete halt in the production of urine.

appendicitis Inflammation of the appendix.

ascites Abdominal edema typically signaling liver failure.

benign prostate hypertrophy (BPH) Age-related nonmalignant (noncancerous) enlargement of the prostate gland.

Boerhaave syndrome A tear in the esophagus that extends entirely through the esophageal wall, creating a hole; caused by forceful vomiting.

cholecystitis Inflammation of the gallbladder.

chronic kidney disease Progressive and irreversible inadequate kidney function as a result of permanent loss of nephrons.

colic Acute, intermittent, cramping abdominal pain.

Crohn disease Inflammation of the ileum and possibly other portions of the gastrointestinal tract, in which the immune system attacks portions of the intestinal walls, causing them to become scarred, narrowed, stiff, and weakened.

cystitis Another name for urinary tract infection.

disequilibrium syndrome A condition characterized by nausea, vomiting, headache, and confusion, which results when, as a consequence of dialysis, water initially shifts from the bloodstream into the cerebrospinal fluid, mildly increasing intracranial pressure.

diverticulitis Inflammation of a diverticulum, usually in the colon, creating abdominal discomfort; a *diverticulum* is an abnormal pouch or sac.

ectopic pregnancy A pregnancy in which the ovum implants somewhere other than the uterine endometrium.

emesis Vomiting.

end-stage renal disease (ESRD) A condition in which the kidneys have lost all ability to function, and toxic waste materials build up in the patient's blood; occurs after acute or chronic kidney disease.

epididymitis An infection that causes inflammation of the epididymis along the posterior border of the testis; a possible complication of male urinary tract infection.

esophageal varices Enlarged veins in the lower esophagus caused by obstruction of the portal vessels leading to increased pressure in esophageal veins and ultimately causing the capillary network of the esophagus to leak.

esophagitis Inflammation of the lining of the esophagus.

gastritis Inflammation of the stomach.

gastroenteritis A family of conditions resulting in diarrhea, nausea, and vomiting; some have infectious causes.

gastroesophageal reflux disease (GERD) A condition in which the sphincter between the esophagus and the stomach opens, allowing stomach acid to move superiorly; can cause a burning sensation within the chest (heartburn); also called acid reflux disease.

guarding Involuntary muscle contractions (spasm) of the abdominal wall; an effort to protect the inflamed abdomen.

hematemesis Vomit with blood; can either look like coffee grounds, indicating the presence of partially digested blood, or contain bright-red blood, indicating active bleeding.

hematochezia The passage of stool in which bright-red blood can be distinguished; caused by lower gastrointestinal bleeding.

hematuria The presence of blood in the urine.

hernia The protrusion of a loop of an organ or tissue through an abnormal body opening.

ileus Paralysis of the bowel, arising from any one of several causes; it stops the contractions that normally move material through the intestine.

internal shunt Also called an arteriovenous fistula, this device is an artificial connection between a vein and an artery, usually in the forearm or upper arm.

irritable bowel syndrome (IBS) A condition in which patients have abdominal pain and changes in their bowel habits; generally, the pain must be present for at least 3 days a month for at least 3 months to be considered this disease.

kidney stones Solid crystalline masses formed in the kidney, resulting from an excess of insoluble salts or uric acid crystallizing in the urine; these masses may become trapped anywhere along the urinary tract.

Mallory-Weiss tear A tear in the mucous membrane, or inner lining, where the esophagus and the stomach meet, causing severe bleeding and potentially death.

melena Dark, tarry, malodorous stools caused by upper gastrointestinal bleeding.

nephrons The structural and functional units of the kidney that form urine; composed of the glomerulus, the glomerular (Bowman) capsule, the proximal convoluted tubule, loop of Henle, and the distal convoluted tubule.

oliguria A decrease in urine output to the extent that total urine output drops to less than 500 mL per day.

orchitis A complication of a male urinary tract infection in which one or both testes become infected, enlarged, and tender, causing pain and swelling in the scrotum.

orthostatic hypotension A drop in systolic blood pressure when moving from a lying or sitting to a standing position.

orthostatic vital signs Assessing vital signs in two different patient positions to determine the degree of hypotension; also known as the tilt test.

pancreatitis Inflammation of the pancreas.

pelvic inflammatory disease (PID) An infection of the female upper organs of reproduction, specifically the uterus, ovaries, and fallopian tubes.

peristalsis Waves of alternate circular contraction and relaxation of the intestines or other tubular structure to propel the contents forward.

peritoneum The membrane lining the abdominal cavity (parietal peritoneum) and covering the abdominal organs (visceral peritoneum).

peritonitis Inflammation of the peritoneum.

portal vein The blood vessel that transports blood from the gastrointestinal tract to the liver.

priapism A painful, tender, persistent erection of the penis; can result from spinal cord injury, erectile dysfunction drugs, or sickle cell disease.

pyelonephritis Inflammation of the kidney and renal pelvis.

rebound tenderness Parietal pain that occurs when pressure is removed rather than applied; suggestive of a serious and potentially life-threatening condition.

referred pain The pain felt in an area of the body other than the area where the cause of pain is located.

renal dialysis A technique for filtering the blood of its toxic wastes, removing excess fluids, and restoring the normal balance of electrolytes.

shunt A passageway that allows fluid to move from one part of the body to another or to a dialysis machine.

steatorrhea Foamy, fatty stools associated with liver failure or gallbladder problems.

strangulation Complete obstruction of blood circulation in a given organ as a result of compression or entrapment; an emergency situation causing death of tissue.

testicular torsion Twisting of the testicle on the spermatic cord, from which it is suspended; associated with scrotal pain and swelling, and is a medical emergency.

ulcerative colitis Generalized inflammation of the inner lining of the colon that results in a weakened, dilated rectum, making it susceptible to infection and bleeding.

ulcers Abrasions of the stomach or small intestine.

uremia The presence of excessive amounts of urea and other waste products in the blood.

uremic frost A powdery buildup of uric acid, especially on the face.

urinary retention Incomplete emptying of the bladder or a complete lack of ability to empty the bladder.

urinary tract infections (UTIs) Infections, usually of the lower urinary tract (urethra and bladder), which occur when normal flora bacteria or other bacteria enter the urethra and grow.

visceral pain Crampy, aching pain deep within the body, the source of which is usually difficult to pinpoint; common with urologic problems.

Chapter 21

Endocrine and Hematologic Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Endocrine Disorders

Awareness that

- Diabetic emergencies cause altered mental status (pp 1085–1090)

Anatomy, physiology, pathophysiology, assessment, and management of

- Acute diabetic emergencies (pp 1081–1089)

Hematology

Anatomy, physiology, pathophysiology, assessment, and management of

- Sickle cell crisis (pp 1095–1097, 1099–1102)
- Clotting disorders (p 1098)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the endocrine system and its main function in the body. (pp 1068–1070)
2. Discuss the role of glucose as a major source of energy for the body and its relationship to insulin. (pp 1070–1071)
3. Compare hypothyroidism with hyperthyroidism. (p 1072)
4. Define the term diabetes. (p 1072)
5. Discuss complications of diabetes. (pp 1073–1075)
6. Distinguish between the two types of diabetes and how their onset patterns differ. (pp 1075–1077)
7. Explain some age-related considerations when managing a geriatric patient who has undiagnosed diabetes. (p 1075)
8. Identify risk factors associated with prediabetes, including the role of hemoglobin A1c blood tests, in distinguishing prediabetes from diabetes. (pp 1077–1078)
9. Discuss diagnosis and management of gestational diabetes. (pp 1078–1079)
10. Explain some age-related considerations when managing a pediatric patient who is experiencing a hyperglycemic or hypoglycemic crisis. (p 1079)
11. Describe the differences and similarities between hyperglycemic and hypoglycemic diabetic emergencies, including their onset, signs and symptoms, and management considerations. (pp 1079–1085)
12. Discuss the steps to follow when conducting a primary survey and secondary assessment of a patient with an altered mental status who is a suspected diabetic patient. (pp 1086–1088)

13. Explain the process for assessing and managing the airway of a patient with an altered mental status, including ways to differentiate a hyperglycemic patient from a hypoglycemic patient. (pp 1086–1087)
14. Describe the interventions for providing emergency medical care during a hypoglycemic crisis to responsive and unresponsive patients who have a history of diabetes. (pp 1089–1090)
15. Describe the interventions for providing emergency medical care during a hyperglycemic crisis to responsive and unresponsive patients with a history of diabetes. (p 1092)
16. Provide the generic and trade names, form, dose, administration, indications, and contraindications for giving oral glucose to a patient with a decreased level of consciousness who has a history of diabetes. (p 1090 and Chapter 12, *Principles of Pharmacology*)
17. Explain when it is appropriate to obtain medical direction when providing emergency medical care to a patient with diabetes. (p 1089)
18. Provide the generic and trade names, form, dose, administration, indications, and contraindications for administering dextrose to a patient with hypoglycemia. (pp 1090–1091 and Chapter 12, *Principles of Pharmacology*)
19. Provide the generic and trade names, form, dose, administration, indications, and contraindications for administering glucagon to a patient with hypoglycemia. (pp 1091–1092 and Chapter 12, *Principles of Pharmacology*)
20. Discuss the composition and functions of blood. (pp 1093–1094)
21. Describe the pathophysiology of sickle cell disease and the four main types of sickle cell crises. (pp 1095–1097)
22. Describe blood clotting disorders and the risk factors, characteristics, and management of each. (p 1098)
23. Describe the assessment and management of a patient with suspected sickle cell disease. (pp 1099–1102)

SKILLS OBJECTIVES

1. Demonstrate the assessment and care of a patient with hypoglycemia and a decreased level of consciousness. (pp 1085–1089)
2. Demonstrate how to administer glucose to a patient with an altered mental status. (p 1090)
3. Demonstrate how to administer dextrose to a patient with hypoglycemia. (pp 1090–1091)
4. Demonstrate how to administer glucagon to a patient with hypoglycemia. (pp 1091–1092)
5. Demonstrate the assessment and care of a patient with sickle cell crisis. (pp 1099–1102)
6. Demonstrate the assessment and care of a patient with a blood clotting disorder. (p 1098)

Introduction

The endocrine system directly or indirectly influences almost every cell, organ, and function of the body. Consequently, patients with an endocrine disorder often are seen with a multitude of signs and symptoms that require a thorough assessment and immediate treatment. This chapter also discusses hematologic emergencies, which rarely occur in most emergency medical services (EMS) systems. Although hematologic disorders can be difficult to assess and treat in a prehospital setting, your actions may not only offer support, but you may save the patient's life.

Anatomy and Physiology Review: The Endocrine System

The major components of the **endocrine system** include the hypothalamus; the pineal gland, pituitary gland, thyroid gland, thymus gland, parathyroid gland, and adrenal glands; the pancreas; and the gonads, including the ovaries and testes.

The endocrine system comprises a network of glands that produce and secrete chemical messengers called hormones. **Hormones** are chemical substances produced by glands that have special

FIGURE 21-1 The endocrine system uses the various glands within the system to deliver chemical messages to organ systems throughout the body.

© Jones & Bartlett Learning.

regulatory effects on other organs and tissues. Hormones travel in the bloodstream to target tissues (**FIGURE 21-1**). Hormones are involved in regulation of mood, growth and development, metabolism, tissue function, and sexual development and function. **Endocrine glands** secrete or release chemicals, such as hormones, inside the body.

The main function of the endocrine system and its hormone messengers is to maintain homeostasis

and promote permanent structural changes. Maintaining homeostasis requires a response to any change in the body, such as low glucose or calcium levels in the blood.

Pituitary Gland

Located at the base of the brain, the pituitary gland is divided into anterior and posterior regions.

YOU are the Provider

Part 1

At 1130 hours, your ambulance is dispatched to an unresponsive 41-year-old man. On arrival, you are greeted by the patient's wife, who states that the patient has a medical history of diabetes. She tells you that as she was fixing lunch, he became confused and then unresponsive. Your primary survey of the patient reveals that he is responsive to deep painful stimuli, with adequate respirations. The patient's wife states that the patient has an insulin pump, but she didn't know if she should turn it off or not.

1. What are the two types of diabetes, and how do they differ?
2. What is the function of an insulin pump?
3. Should you instruct the patient's wife to turn off the insulin pump?

Six of the hormones secreted by the pituitary gland stimulate other endocrine glands and are referred to as tropic (from the Greek *tropos*, meaning “to turn” or “change”) hormones. These include adrenocorticotrophic hormone (ACTH), follicle-stimulating hormone, growth hormone, luteinizing hormone, prolactin, and **thyroid-stimulating hormone**. The other two hormones, antidiuretic hormone and oxytocin, control other body functions.

During times of stress, the hypothalamus secretes a hormone that stimulates the anterior pituitary to release ACTH. ACTH targets the adrenal cortex and causes it to secrete **cortisol**. Cortisol stimulates most body cells to increase their energy production.

Thyroid Gland

Thyroid hormones, which affect metabolism, are secreted in response to stimulation of the thyroid gland by the anterior pituitary gland. The anterior pituitary gland secretes thyroid-stimulating hormone in response to the hypothalamus’s secretion of thyrotropin-releasing hormone.

The thyroid gland secretes thyroxine (T_4) when the body’s metabolic rate decreases. Thyroxine, the body’s major metabolic hormone, stimulates energy production in cells, which increases the rate at which cells consume oxygen and use carbohydrates, fats, and proteins. Without the proper intake level of dietary iodine, thyroxine cannot be produced, and the patient’s physical and mental growth are diminished.

The thyroid gland also secretes **calcitonin**, which helps maintain normal calcium levels in the blood. This hormone is secreted when the thyroid detects high levels of calcium. Calcitonin travels to the bones, where it stimulates the bone-building cells to absorb the excess calcium. It also stimulates the kidneys to absorb and excrete excess calcium.

Pancreas

The **pancreas** is considered both an endocrine gland and an **exocrine gland**. It has a role in hormone production as well as in digestion. The exocrine component secretes digestive enzymes into the duodenum via the pancreatic duct. The endocrine component secretes hormones from cell groups called the **islets of Langerhans**. These cell groups within the pancreas act like an organ within an organ,

FIGURE 21-2 The islets of Langerhans secrete hormones into blood vessels that modulate serum glucose levels.

© Jones & Bartlett Learning.

secreting the polypeptide hormones **glucagon** (from alpha cells, and which raises blood glucose levels), **insulin** (from beta cells, and which lowers blood glucose levels), and somatostatin (from delta cells, and which is responsible for the inhibition of insulin and glucagon secretion) (**FIGURE 21-2**). In a healthy patient, the body regulates blood glucose levels using both insulin and glucagon.

The Role of Glucose and Insulin

Glucose, or dextrose, is one of the basic sugars in the body and, along with oxygen, is the primary fuel for cellular metabolism. Glucose is the major source of energy for the body, and all cells need it to function properly. Some cells will not function at all without glucose. The brain needs a constant supply of glucose, just as it does oxygen. Without glucose, or with an extremely low glucose level, brain cells rapidly suffer permanent damage. A normal blood glucose level in nonfasting adults and children is approximately 80 to 120 mg/dL.

Special Populations

The normal range for glucose levels in blood in nonfasting children is the same as adults: 80 to 120 mg/dL. The blood glucose level in neonates should be above 80 mg/dL.

Insulin is a hormone produced by the pancreas that facilitates the uptake of glucose from the bloodstream into the cell. In all areas of the body except

FIGURE 21-3 The alpha, beta, and delta cells are in the islets of Langerhans, which are in the pancreas.

© Jones & Bartlett Learning.

for the brain, insulin is needed to allow glucose to enter individual cells to fuel their functioning. For this reason, insulin is said to be a cellular key.

Regulation of glucose levels in the body is a complex and dynamic process that begins when absorbed carbohydrates stimulate the release of insulin from the beta cells of the islets of Langerhans in the pancreas (**FIGURE 21-3**). Insulin is responsible for the removal of glucose from the blood for storage as glycogen, fats, and protein.

When blood glucose levels are elevated, the following process occurs:

- The islets of Langerhans secrete insulin, which is carried by the bloodstream to the cells.
- Insulin increases cell membrane permeability and mediates the transport of glucose across the cell membrane into the cells, where it is used to produce energy.

- The cells use glucose to produce energy through processes that include **glycolysis**, the conversion of glucose into energy via metabolic pathways, and the Krebs cycle. (When oxygen is present during this process, **aerobic metabolism** occurs, the by-products of which are carbon dioxide and water.) More on the physiology of metabolism can be found in Chapter 7, *The Human Body*.

Insulin also stimulates the liver to store excess glucose and the skeletal muscles store glycogen for later use by the body. Insulin is the only hormone that decreases blood glucose levels. After blood glucose levels have returned to normal, the islets of Langerhans discontinue the secretion of insulin.

Words of Wisdom

The brain is the only organ that can utilize glucose without insulin.

When the blood glucose level decreases, such as between meals, the following process occurs:

- The alpha cells of the islets of Langerhans release the hormone glucagon.
- When glucagon enters the bloodstream, it raises the blood glucose level and brings the body's energy back to normal by stimulating the liver to convert stored glycogen back into glucose through a process called **glycogenolysis**.
- The glucose is secreted into the bloodstream, where cells can use it for energy.
- If stored glycogen levels are depleted, the cells begin to metabolize fats, proteins, and other noncarbonate sources, thus producing new glucose—a process called **gluconeogenesis**.

In healthy endocrine systems, these shifts in metabolism are tolerated and never allowed to proceed to extremes.

Pathophysiology of the Endocrine System

Endocrine disorders can be caused by either hypersecretion or insufficient secretion of a gland. Hypersecretion presents as overactivity of the target

TABLE 21-1 Comparison of Major Effects of Hypothyroidism and Hyperthyroidism

	Hypothyroidism	Hyperthyroidism
Cardiovascular effects	Slow pulse, reduced cardiac output	Rapid pulse, increased cardiac output
Metabolic effects	Decreased metabolism, cold skin, weight gain	Increased metabolism, skin hot and flushed, weight loss
Neuromuscular effects	Weakness, sluggish reflexes	Tremor, hyperactive reflexes
Mental, emotional effects	Mental processes sluggish, personality placid	Restlessness, irritability, emotional lability
Gastrointestinal effects	Constipated	Diarrhea
General somatic effects	Cold, dry skin	Warm, moist skin

© Jones & Bartlett Learning.

organ regulated by the gland. Insufficient secretion results in underactivity of the organ controlled by the gland. Hyperthyroidism and hypothyroidism are two serious illnesses of the endocrine system. However, most of the endocrine emergencies you will encounter will be related to diabetic emergencies secondary to abnormal insulin secretion.

Hypothyroidism and Hyperthyroidism

Hyperthyroidism increases metabolism, while hypothyroidism decreases metabolism. **TABLE 21-1** summarizes the major effects of hypothyroidism and hyperthyroidism. Although approximately 20 million Americans have some type of thyroid disorder,¹ many are unaware of their condition. Treatment of these patients should be symptomatic with transport to the closest most appropriate facility.

Words of Wisdom

Thyroid storm is a rare, life-threatening condition that may occur in patients with thyrotoxicosis (a toxic condition caused by excessive levels of circulating thyroid hormone). The condition is usually triggered by a stressful event or increased volume of thyroid hormones in the circulation. In addition to the normal signs and symptoms of hyperthyroidism, patients may present with fever, severe tachycardia, nausea, vomiting, altered mental status, and possibly heart failure.

Diabetes Mellitus

Diabetes is a metabolic disorder that is now thought to be associated with a group of complex diseases with many causes (ie, **diabetes mellitus** [a disease characterized by the body's inability to sufficiently metabolize glucose], **gestational diabetes** [diabetes that develops during pregnancy in women who did not have diabetes before pregnancy], hypoglycemia/hyperglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome). These pathologic conditions reflect a flaw in the production or function of insulin, or both. Insulin assists in the metabolism of carbohydrates and the transport of glucose into the cells. The end result of diabetes is hyperglycemia, also known as high blood glucose. Medically, the term *diabetes* refers to a metabolic disorder in which the body's ability to metabolize simple carbohydrates (glucose) is impaired. It is characterized by the following symptoms:

- **Polyphagia**, an increased appetite caused by the inability of glucose to be transported across the cell membrane.
- **Polydipsia**, a substantial thirst caused by dehydration brought about by an increase in diuresis (the production of large amounts of urine by the kidney).
- **Polyuria**, the passage of large quantities of urine. In diabetes, excess glucose is excreted in the urine (glycosuria) and attracts water, resulting in excessive diuresis.

Diabetes mellitus is characterized by the body's inability to sufficiently metabolize glucose.

Mellitus, from the Greek word for honeybee, means “sweet”—a reference to the presence of glucose in the urine. In people with this disease, the pancreas does not produce enough insulin or the body’s cells do not respond to the effects of the insulin that is produced. In either case, the result is the same: an elevated level of glucose in both the blood and the urine. Glucose builds up in the blood, overflows into the urine, and flows out of the body. Because the lack of effective insulin prevents the sugar from moving inside the cells where it can be metabolized, cells can actually starve, or be deprived of glucose, even when the blood contains large amounts of glucose (FIGURE 21-4).

According to the Centers for Disease Control and Prevention (CDC), more than 30 million people in the United States (almost 10% of the population) have diabetes.² Another 1.5 million Americans are diagnosed with diabetes each year, and it is thought that many more have undiagnosed diabetes.³ In 2017, diabetes was the seventh leading cause of death in United States, although the CDC suggests diabetes may be underreported as a source of mortality.^{2,3}

Diabetes mellitus is responsible for myriad life-altering complications, some of which are listed here:

- **Kidneys.** Diabetes is the principal cause of kidney failure.⁴ The glomeruli of the kidney become sclerotic, causing necrosis of the papillary tissue and resulting in nephropathy (end-stage renal disease) and renal failure. High levels of glucose in the blood cause the kidneys to work harder than normal and can result in decreased kidney function over time.
- **Heart.** Adults with diabetes are approximately two times more likely to die of heart disease or to experience a stroke than those who do not have diabetes.⁵ When diabetes is poorly controlled, the process of **lipolysis** (from *lipo-*, meaning “fat,” and *-lysis*, meaning “break-down”) raises the level of fat in the blood. As a result of the raised fat level, the risk of atherosclerosis and coronary artery disease increases. The fat circulating through the bloodstream adheres to the vessel walls, eventually causing them to be stiff and brittle. In addition, glucose crystals are sharp and can damage the blood vessels. The microscopic deterioration of the vessel walls, called **microangiopathy**, results in

FIGURE 21-4 Diabetes is defined as a lack of or ineffective action of insulin. Without insulin, cells begin to starve because insulin is needed to allow glucose to enter and nourish the cells.

© Jones & Bartlett Learning.

swelling of basement membrane cells, which then restricts the flow of blood to organs and tissues. Inadequate blood flow (ischemia) causes necrosis, or tissue death. Autonomic nervous system dysfunction can cause cardiac dysrhythmias, which can result in cardiac arrest and sudden death. Microangiopathy and nerve damage contribute to an increased risk for a *silent* myocardial infarction to be experienced by a patient with diabetes. These pathologies combine and result in the patient

with diabetes not perceiving the common signs of chest pain, pressure, or tightness often associated with an acute myocardial infarction (AMI). Therefore, an AMI should always be assumed until proved otherwise for any patient with diabetes who reports a syncopal episode, fainting, weakness, fatigue, malaise, or dyspnea on exertion.

- **Circulatory system.** Microangiopathy results in cerebrovascular disease and an increased incidence of stroke. Hypertension is present in most people with diabetes. Hypertension further increases the risk of heart disease, stroke, kidney disease, and blindness.

Peripheral artery disease is also common in people with diabetes and impairs circulation to the lower extremities (**FIGURE 21-5**).

- **Eyes.** In adults age 20 to 74 years, diabetes is the chief cause of new cases of blindness as a result of retinopathy.⁶ High glucose levels in the blood damage the vessels of the eye, causing swelling, wall weakness, and obstruction.

FIGURE 21-5 Peripheral edema and poor circulation are complications associated with long-term diabetes.

Courtesy of Rhonda Hunt.

Scar tissue can form that causes a pulling of the retina from the eye, or retinal detachment. Cataracts are a cloudy film that forms when fructose and sorbitol are deposited in the lens of the eye.

- **Neuropathy.** Neuropathy is nerve damage that results in a loss of sensation and function in the area innervated by the affected nerves. Such damage can cause sexual impotence, neurogenic bladder, constipation, or diarrhea. Neuropathy associated with diabetes often affects peripheral nerves, causing diminished sensation and function in the extremities. Patients with peripheral neuropathy often have paresthesia, a pinprick sensation in the hands, feet, arms, or legs. Paresthesia and dysesthesia (the absence of sensation) can blunt pain perception, making it possible for foot ulcers to go unnoticed until they become seriously infected. Because many of these patients also have poor circulation in the extremities, gangrene can develop in adjacent tissues and infection may spread to the bone. In fact, diabetes is commonly the cause of nontraumatic lower limb amputations.⁴

Because of the widespread effect of diabetes on all systems of the body, any preexisting condition will be more difficult to manage after diabetes develops in the patient. The more closely patients adhere to the recommended management of their diabetes, the better the outcome of their other conditions will be. Conditions that develop subsequent to the onset of diabetes will respond more effectively when diabetes is managed appropriately. Many conditions associated with the presence of diabetes can be delayed or prevented with appropriate lifestyle changes and continued management of diabetes. Conversely, any kind of distress can have a negative effect on the patient and result in a 9-1-1 call because blood glucose levels are more difficult to control in the setting of increased physical activity or emotional stress.

Both chronic and acute complications are associated with diabetes mellitus. Although these complications are present in both forms of the disease (type 1 and type 2), they tend to be more severe in people with diabetes who require insulin. Left untreated, diabetes results in organ system dysfunction, wasting of body tissues, and death. Even with excellent medical care, some patients with

particularly aggressive forms of diabetes will die at a relatively young age from complications of the disease. The severity of diabetic complications correlates with the average blood glucose level and the age of onset. Although some patients with well-controlled diabetes have a normal life span, they must be willing to adjust their lives to the demands of the disease, especially their eating habits and physical activity levels. There is no cure for the disease, so treatment focuses on maintaining the level of blood glucose within the patient's normal range.

Two forms of diabetes mellitus exist: type 1 (formerly known as juvenile-onset diabetes) and type 2 (formerly known as adult-onset diabetes). The age of onset of the patient's symptoms is less important than whether the patient requires insulin to survive.

Special Populations

You might encounter an older adult patient who has undiagnosed diabetes. These patients report that they have not been feeling well for a while but have not seen a physician. A patient with undiagnosed diabetes or one who is in denial or ignores the advice of their physician may call 9-1-1 when the signs and symptoms get worse. Nonhealing wounds, blindness, renal failure, and other complications are associated with poorly controlled or uncontrolled diabetes. It is important that you recognize the signs and symptoms of diabetes because you might be the first health care provider to suggest medical treatment to an older adult patient who might otherwise ignore the condition.

Older adult patients and those with diabetes commonly present atypically with an AMI. They often do not present with classic crushing substernal chest pain or pressure because of the neuropathy associated with increasing age and diabetes. Older adults also generally have a higher pain tolerance than do younger patients. Other causes of an altered perception of pain can include impaired cognition or slowed nerve conduction. You should maintain a high index of suspicion when these populations experience a syncopal episode, fatigue, shortness of breath, or nausea and diaphoresis.

Older adult patients are also more susceptible to dehydration and infections. As we age, our bodies tend to lose approximately 10% of the total body fluid. Older adult patients may not become thirsty or react to thirst until they are extremely dehydrated. Medications can also cause an increase in diuresis, compounding the problem.

Both types of diabetes mellitus are serious conditions that affect many tissues and functions other than the glucose-regulating mechanism, and both require lifelong medical management. In addition, the condition known as **prediabetes** is now recognized as a warning sign that may precede the development of type 2 diabetes, and is discussed later in this chapter.

Type 1 Diabetes Mellitus

As mentioned, **type 1 diabetes** has historically been referred to as insulin-dependent diabetes mellitus or juvenile-onset diabetes because it generally affects children. Although type 1 diabetes has a hereditary predisposition, it is believed that environmental factors may play a role—for example, with an infection that triggers an autoimmune disorder. With type 1 diabetes, the body develops autoantibodies that incorrectly identify the body's own tissues or substances as foreign invaders to be destroyed. Contributing to pancreatic destruction are autoantibodies to the insulin-secreting beta cells in the islets of Langerhans, to insulin, and to other pancreatic substances. The rate of beta cell destruction is variable, occurring rapidly in some patients (mainly children) and slowly in others (mainly adults).⁷ Eventually, the pancreatic beta cells become incapable of secreting insulin and regulating intracellular glucose. Because beta cells are the only source of insulin, it must then be administered by injection or with a pump when the cells are destroyed.

Latent autoimmune diabetes in adults is a variant of type 1 diabetes that occurs in adults older than 30 years. The pathophysiology is the same as that of young-onset diabetes, with the body's immune system destroying the beta cells. Thus, adult patients with latent autoimmune diabetes will ultimately require insulin therapy.

When the endocrine system (or pancreas) fails to produce insulin (as is the case in most patients with type 1 diabetes), people require daily injections of supplementary, synthetic insulin throughout their lives to control their blood glucose levels. In addition to daily insulin injections, strict dietary control must be observed, which can be difficult to achieve with young children. Increased activity and alcohol consumption can result in low blood glucose levels (alcohol depletes glycogen stores in the liver). Therefore, in adults with type 1 diabetes, alcohol consumption also must be controlled.

FIGURE 21-6 An insulin pump is a small electronic device that automatically delivers insulin to maintain the desired blood glucose level.

© Photographee.eu/Shutterstock.

In terms of management, type 1 diabetes always requires the use of insulin that is administered by injection or an insulin pump, also called continuous subcutaneous insulin infusion therapy. Insulin cannot be ingested orally because the digestive process will render it inactive.

You will likely encounter patients with diabetes who use insulin pumps to treat their disease. An alternative to multiple daily injections of insulin, insulin pumps provide improved control of blood glucose levels and better quality of life for many patients. These small devices consist of an infusion set, a reservoir for insulin, and the pump itself. The pump is approximately the size of a deck of cards, weighs approximately 3 ounces, and can be worn on a belt or carried in a pocket (**FIGURE 21-6**). Insulin is administered through a catheter under the skin. The pump is often set to deliver a basal amount of insulin continuously throughout the day. Alternatively, the pump can be set to deliver a bolus of insulin at specific times such as mealtimes, when blood glucose levels are high.

Special Populations

Pediatric patients with type 1 diabetes are susceptible to seizures and dehydration in hyperglycemia. In late stages of hyperglycemia, cerebral edema may also develop. Treat pediatric patients with an altered mental status aggressively and provide rapid transport.

Type 2 Diabetes Mellitus

The most common form of diabetes is **type 2 diabetes** (sometimes called adult-onset diabetes), in which blood glucose levels are elevated because the body becomes resistant to the insulin produced and cannot produce enough insulin to overcome that resistance effectively. Type 2 diabetes can also be caused by a deficiency in insulin production. Type 2 diabetes typically develops when a person is middle aged, although the disease is becoming more common in younger people.

In some cases, an abnormal increase in glucose production by the liver causes an increase in blood glucose levels. Normally, when blood glucose and insulin levels are low, the pancreas releases glucagon and stimulates the liver to produce and release glucose into the blood. In some people, however, the levels of glucagon stay high. When glucagon levels remain high, excess amounts of glucose are produced, resulting in high blood glucose levels.

According to the World Health Organization, approximately 8.5% of the world's population is affected by diabetes, mostly type 2, making it a global health concern.⁸ Approximately 90% of all people with diabetes in the United States have type 2 diabetes.⁴ The development of type 2 diabetes has been associated with obesity and physical inactivity, two characteristics becoming more common in today's populations.

Symptoms of untreated type 2 diabetes may include the following:

- Fatigue
- Nausea
- Frequent urination
- Thirst
- Unexplained weight loss
- Blurred vision
- Frequent infections and slow healing of wounds
- Being cranky, confused, or shaky
- Unresponsiveness
- Seizure

These symptoms tend to develop gradually and usually become noticeable in middle age. In fact, the onset of type 2 diabetes may be so insidious that patients may not realize they have the disease. In some instances, the symptoms can develop over several years in overweight adults older than 40 years. A small percentage of patients do not display any symptoms.

Weight loss is an important factor in helping to control type 2 diabetes. Exercise and a well-balanced, nutritious diet are key components in combating the complications of diabetes. To maintain glucose levels within the normal range, food intake must be spread throughout the day in coordination with daily oral medications and/or insulin injections and monitoring of glucose levels with a glucometer (**FIGURE 21-7**). Metformin, the medication most commonly prescribed for the management of type 2 diabetes, causes a decrease in glucose production. You can help patients by reinforcing this message to the patient and by helping the family understand how to reduce the patient's risk of diabetic complications.

Prediabetes

As mentioned, *prediabetes* is a condition identified in people who have certain risk factors associated with type 2 diabetes and exists when blood glucose levels or hemoglobin A1c levels are above normal levels, yet not high enough to be diagnosed as diabetes. The A1c blood test reveals information about the patient's blood glucose levels over the prior 3 months. A normal A1c level is less than 5.7%,

prediabetes is diagnosed with an A1c level between 5.7% and 6.4%, and type 2 diabetes is diagnosed with an A1c level greater than 6.4%. A patient with uncontrolled diabetes over a long period may have a level higher than 8%.⁹ The goal for a diabetic patient is an A1c level of 7% or less.

According to the CDC, prediabetes affects 1 out of 3 adults in the United States, or approximately 86 million people, and 90% are unaware of their status. Within 5 years and with no intervention, 15% to 30% of people with prediabetes will develop type 2 diabetes. Risk factors for experiencing this disease course include the following characteristics:¹⁰

- Older than 45 years
- Being overweight
- A family history of diabetes—specifically, a parent or sibling who has been diagnosed as having type 2 diabetes
- Being of African American, Hispanic/Latino, American Indian, Pacific Islander, and some Asian American racial or ethnic backgrounds
- Gestational diabetes or having given birth to a baby who weighed more than 9 pounds (4 kg)
- Being physically active fewer than 3 times per week

YOU are the Provider

Part 2

Recognizing that this patient is probably hypoglycemic, you instruct the patient's wife to turn off the insulin pump. After the pump is turned off, you proceed to check the patient's blood glucose level, to which your glucometer displays "Lo." The reading from the glucometer confirms your suspicion that the patient is experiencing an acute hypoglycemic episode. Because the patient has a decreased level of consciousness, the administration of oral glucose is contraindicated. You ask your partner to place the patient on a nonbreathing mask and administer oxygen at 15 L/min. Finding a large vein in the patient's arm, you establish an 18-gauge intravenous (IV) line and ensure that the line is patent as you prepare a 50% dextrose (D₅₀) solution.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Responsive to deep painful stimuli
Airway	Patent
Breathing	12 breaths/min
Circulation	Strong radial pulse; skin is warm and dry

4. By which route or routes may D₅₀ be administered?
5. What are the indications and contraindications for dextrose?
6. What is the usual adult dosage of dextrose?

Words of Wisdom

A portion of the glucose in the blood attaches to the hemoglobin and is called hemoglobin A1c (HbA1c). The higher the glucose level in the bloodstream, the higher the amount that binds to the hemoglobin. Because the red blood cells (RBCs) live and circulate in the bloodstream for several months, a measurement can be obtained that determines the average level of blood glucose over a couple of months.

The hemoglobin A1c test does not require fasting and can be performed at any time of the day. Factors that affect hemoglobin may alter accurate A1c test results, and include the following:

- Heavy or chronic bleeding may deplete hemoglobin stores and result in falsely low A1c results.
- Iron-deficiency **anemia** may cause A1c results to be falsely high.
- Recent blood transfusions or hemolytic anemia may result in falsely low results.
- People with an uncommon form of hemoglobin, known as a hemoglobin variant, may have test results that are falsely low or falsely high. This is most often found in people of African, Mediterranean, or Southeast Asian descent. In such cases, tests should be performed at specialized labs for the most accurate results.
- People with kidney or liver failure, or who have a family history of sickle cell anemia, may also have inaccurate A1c results.

Although some of the risk factors affecting the pathway from prediabetes to type 2 diabetes cannot be altered, others can. According to the CDC, interventions affecting two specific factors can help prevent or delay the onset of type 2 diabetes by 58%, specifically, losing 5% to 7% of the patient's body weight and getting at least 150 minutes of physical activity per week.¹¹

Gestational Diabetes

Gestational diabetes does not have a pancreatic component, but rather is a form of glucose intolerance that can occur during pregnancy. This condition has been identified more often in African American, Hispanic/Latino, and Native American populations, as well as in women with obesity or who have a family history of diabetes. Women who experience gestational diabetes during pregnancy have a 40% to 60% increased risk of developing

A

type 2 diabetes within one decade.^{12,13} For most women, gestational diabetes will resolve before delivery. In a few women, however, diabetes will not resolve or type 2 diabetes will develop.

Blood glucose crosses the placental barrier. When a pregnant woman is hyperglycemic, high levels of glucose enter the fetus, causing increased production of insulin by the fetus in an attempt to normalize blood glucose levels. The extra glucose is converted into fat in the fetus, such that women experiencing gestational diabetes often deliver large babies (macrosomia) and may encounter difficult deliveries. Often, cesarean sections are required.

Gestational diabetes is usually diagnosed at 28 weeks' gestation and peaks in the third trimester of pregnancy. It is thought that two hormones produced by the placenta, progesterone and estrogen, result in *insulin resistance*. Because this condition typically occurs later in pregnancy, the risk of birth defects is lower. Infants of mothers in whom gestational diabetes developed are at higher risk for obesity and diabetes in their lifetime.

Words of Wisdom

The oral glucose tolerance test is used to diagnose gestational diabetes. This test should be used until the pregnant woman is within 12 weeks of delivery. The hemoglobin A1c test can be used during the first pregnancy visit to identify the presence of preexisting diabetes or prediabetes.

Management of gestational diabetes should be initiated as soon as possible to stabilize blood glucose levels and minimize potential complications to both mother and baby. Management includes diet modification, exercise, and blood glucose testing. Oral medications are not prescribed for this form of diabetes, and insulin injections may be required.

Hypoglycemia

Hypoglycemia in a person with type 1 diabetes is often the result of having taken too much insulin, too little food, or both. The tissues of the central nervous system (including the brain), unlike other tissues that can usually metabolize fat or protein in addition to sugar, depend entirely on glucose as their source of energy. If the level of glucose in the

blood decreases dramatically, the brain is literally starved. **Hypoglycemic crisis**, also known as *insulin shock*, is the result of hypoglycemia, or insufficient glucose in the blood.

Counterregulation is the body's natural defensive ability to maintain blood glucose at an appropriate level. An understanding of this concept is critical because it will help you treat (and ideally prevent) severe hypoglycemia.

The body's first line of defense against low blood glucose is to reduce insulin production by the pancreas and to increase glucagon production by the alpha cells. When cells are deprived of glucose, a distress signal goes out over the sympathetic nervous system, causing the release of various stress hormones. The body's second line of defense is the secretion of catecholamines, including epinephrine and norepinephrine, by the adrenal gland. The effects of this catecholamine release can be seen as tachycardia and diaphoresis in the hypoglycemic patient. This second line of defense also includes cortisol, an adrenocorticoid (a steroid produced in the adrenal gland). Cortisol release results in an increase in blood glucose levels, which counteracts insulin's actions. Other hormones produced by the intestine and growth hormone produced by the pituitary gland also increase blood glucose levels.

Last, stimulation of the autonomic nervous system generates signals that allow production of counterregulatory hormones to increase. The same stimulation also triggers symptoms telling the body that the blood glucose level is low; ideally, the affected patient will recognize these symptoms and consume a source of sugar to remedy the imbalance. In response to the action of these hormones, the body mobilizes fatty acids and amino acids from adipose and muscle, respectively. The liver uses these products to make new glucose for the body in a process called gluconeogenesis.

In patients with type 1 diabetes, the islets of Langerhans do not make insulin. As a result, the body's first line of defense against hypoglycemia is lost because the ability to decrease insulin levels via this mechanism is not possible. Often, a low blood glucose level in a patient with diabetes is caused by an elevated level of exogenous insulin (insulin prescribed to the patient for injection) from inaccurate dosing, intentional overdose, or perhaps a mismatch with carbohydrate intake and exogenous insulin intake. In addition, increased use of glucose, such as

what occurs during exercise, causes the blood glucose level to drop sharply, resulting in hypoglycemia.

In patients with type 2 diabetes, the pancreas can generate insulin, so these patients can produce insulin from within their own bodies. However, their bodies may be resistant to the effects of insulin, or they may not make enough insulin over time to lower the blood glucose level adequately. Medications given to treat type 2 diabetes act by either stimulating the body's ability to secrete insulin or by improving insulin's actions. These medications also tend to contribute to hypoglycemia, especially in certain groups of patients such as older adults and those who are not metabolizing these medications properly because of liver or kidney disease. Often, if the hypoglycemia is caused by excessive insulin dosing by the patient or by the prolonged or exaggerated effects of oral diabetes medications, the low blood glucose level will have a prolonged effect and more long-term treatment may be needed.

Some patients who have had type 1 diabetes for many years, and to a lesser degree, patients who have had type 2 diabetes for many years, may not experience a glucagon release from the pancreas in response to hypoglycemia.¹⁴ Lack of glucagon response makes the body more dependent on epinephrine to overcome the effects of hypoglycemia, yet there may be some lack of responsiveness to epinephrine in diabetes as well.^{15,16} Prolonged disease can also decrease a patient's ability to recognize having a low blood glucose level (a state called hypoglycemic unawareness), preventing the patient from taking the necessary measures of self-treatment.

The patient with hypoglycemia will experience trembling; a rapid heart rate; rapid, shallow respirations; sweating; and a feeling of hunger. The brain is highly sensitive to glucose levels, and so these symptoms reflect both the disordered function of hungry brain cells and the alarm reaction (sympathetic nervous system discharge) set off by the brain's distress signals. If hypoglycemia persists, cerebral dysfunction progresses quickly to permanent brain damage.

Some of the most common signs and symptoms of hypoglycemia include the following:

- Blood glucose level less than 70 mg/dL
- Hunger
- Agitation, irritability, or combative behavior that cannot be explained

- Altered mentation or confusion
- Nausea
- Weakness, dizziness, or fainting
- Tachycardia (poor cardiac output)
- Cool, clammy skin

Additional signs and symptoms associated with hypoglycemia include headache, mental confusion, memory loss, incoordination, slurred speech, irritability, dilated pupils, and seizures and coma in severe cases.

Hypoglycemia is a common problem experienced by patients with either type 1 or type 2 diabetes. It develops *rapidly*, over a period ranging from minutes to a few hours, and should be suspected in any patient with diabetes who presents with bizarre behavior, neurologic signs such as altered mental status or weakness or facial drooping similar to a stroke, or coma. Often, a hypoglycemic patient appears intoxicated because of slurred speech and lack of coordination, and may be paranoid, hostile, and aggressive.

Although it is not completely preventable, hypoglycemia can be treated easily. This condition can be detected with regular blood glucose monitoring and rarely results in complications for the patient if identified and treated promptly.

In contrast, severe hypoglycemia, resulting in loss of consciousness or altered mental status, is a more common reason for a call to 9-1-1 and requires intervention and treatment. As an EMS professional, you will need to promptly provide treatment to these patients. If untreated or not detected, serious hypoglycemia can result in coma or death.

Words of Wisdom

The longer a patient remains unresponsive from hypoglycemia, the more likely there will be permanent brain damage! If more than 20 to 30 minutes go by, toxic compounds (free radicals) are produced in the brain that can cause permanent damage.

Of course, people with diabetes are not the only ones who are likely to have episodes of hypoglycemia. Patients with alcoholism, patients who have ingested certain poisons or overdosed with certain drugs (notably aspirin), and patients with

certain cancers, liver disease, kidney disease, and some other conditions may also experience hypoglycemic episodes. Do not discount the possibility of hypoglycemia in a comatose patient just because the patient is not known to have diabetes. Conversely, do not let a known diagnosis of diabetes prevent you from considering other causes of coma. People with diabetes can also experience head injury, stroke, seizures, meningitis, and other traumatic injuries or conditions; the presentation of these conditions may appear similar to diabetic emergencies. Keep an open mind and assess the patient thoroughly.

Words of Wisdom

A patient experiencing a hypoglycemic event may be confused with a patient having a cerebrovascular accident (CVA). D₅₀ is *contraindicated* in CVA in the presence of normal blood glucose levels. Thus, the blood glucose level should be assessed and verified carefully in patients with signs associated with CVA prior to administering D₅₀. The hypertonic properties of D₅₀ may result in increased cerebral edema in the event of a cerebrovascular event.

Hyperglycemia and Diabetic Ketoacidosis

Without insulin, glucose from food remains in the blood and gradually rises to extremely high levels. Normally, high carbohydrate levels are tolerated and return to normal by means of metabolic pathways. Problems arise when the blood glucose level remains elevated and the mechanisms that normally correct this have failed. This condition is called **hyperglycemia**. Hyperglycemia can be caused by excessive food intake, insufficient insulin dosages, infection or illness, injury, surgery, and emotional stress. **Hyperglycemic crisis**, also known as diabetic coma, is a state of unresponsiveness resulting from several problems, including ketoacidosis, hyperglycemia, and dehydration because of excessive urination.

Common early signs include frequent and excessive thirst accompanied by frequent and excessive urination. Hyperglycemia occurs when blood glucose levels exceed the normal range (80 to 120 mg/dL).

Onset of hyperglycemia may be rapid (within minutes) or gradual (hours to days), depending on the cause. For example, excessive food intake may cause blood glucose levels to increase quickly, whereas an infection or illness will result in hyperglycemia over the course of several days.

Some patients with type 2 diabetes can go undiagnosed for several years. Over time, however, repeated episodes of hyperglycemia will cause several physiologic changes that have detrimental long-term effects. Largely because of the increased hyperosmolarity it causes, hyperglycemia puts undue strain on the cardiovascular system, kidneys, and other end organs that are sensitive to increased serum viscosity and the subsequent pressures exerted by the thicker serum. The eventual result is an increased incidence of disorders such as renal failure, heart failure, retinopathy, coronary artery disease, and neuropathy.

When serum glucose levels rise above tolerable levels, physiologic changes occur. These changes represent actual pathologic conditions called **diabetic ketoacidosis (DKA)** (blood glucose level >250 mg/dL, pH level <7.30, and bicarbonate level ≤18 mEq/L) and **hyperosmolar hyperglycemic nonketotic syndrome (HHNS)** (blood glucose level >600 mg/dL, plasma effective osmolarity >320 mOsm/L, and absence of significant ketoacidosis). DKA is associated predominately with people with type 1 diabetes. A life-threatening condition, DKA occurs when certain acids accumulate in the body because insulin is not available (**FIGURE 21-8**). Common causes of DKA include infection, injury, alcohol use, emotional distress, and illness such as stroke or myocardial infarction. In patients with DKA, hyperglycemia continues—that is, glucose continues to accumulate in the blood. Eventually, the patient undergoes massive osmotic diuresis (passing large amounts of urine because of the high solute concentration of the blood).

The process of excreting so much glucose in the urine requires a large amount of water. The loss of water in such large amounts causes the classic symptoms of uncontrolled diabetes, the “3 Ps”: polyuria, polydipsia, and polyphagia. This, together with vomiting, causes dehydration and even shock. Along with water, the body also loses electrolytes (sodium and potassium), which may result in disturbances in water balance and acid-base balance.

FIGURE 21-8 The two most common diabetic emergencies, diabetic ketoacidosis and hypoglycemic crisis, occur when the patient has too much or too little glucose in the blood, respectively. The left side illustrates blood glucose levels; the right side illustrates the conditions associated with that particular level of blood glucose. Notice that the normal range is rather small in comparison to the other ranges.

© Jones & Bartlett Learning.

Words of Wisdom

In DKA, the body does not have sufficient insulin to transport glucose into the cells. Therefore, it uses stored fat as an energy source, producing ketones and acids as waste products. This increase in acids causes a decrease in the body's pH level, resulting in metabolic acidosis. The body must then rely on its buffer systems to attempt to return the pH balance to normal.

The chemical buffer system initially breaks down the acid into a form that can be readily expelled from the body. Remember that with metabolic acidosis, the compensatory mechanism is the respiratory system. Because carbon dioxide is an acid, an increase in the rate and depth of respirations (Kussmaul respirations) will attempt to decrease the amount of acid in the body.

Without glucose to supply energy for cells, the body must turn to other fuel sources, the most abundant of which is fat. Unfortunately, when fat is used as an immediate energy source, chemicals called ketones and fatty acids are formed as waste products and are difficult for the body to excrete.

Fatty acids are broken down primarily by the mitochondria in liver cells. As part of this process, ketone bodies are released into the bloodstream. Large quantities of ketone bodies in the bloodstream cause a decrease in the blood's pH and result in metabolic **acidosis**. This acidosis triggers the body's attempts to buffer the acidity with bicarbonate (HCO_3^-), and the blood pH decreases because of the inability to keep up with the ongoing acidity. In addition to fat tissue breaking down its stores of energy, muscle tissue mobilizes its stores in an effort to create more glucose for the body. This process creates amino acids that may be used by the liver to make glucose (gluconeogenesis). In addition, lactate increases in the bloodstream and contributes to lowering the body's pH. This form of acidosis is known as DKA.

The ketones are responsible for the sweet, fruity breath odor associated with DKA. When the acid levels in the body become too high, individual cells will cease to function. If the patient is not given proper fluid rehydration and insulin to reverse fat metabolism and restore the use of glucose as a source of energy, ketoacidosis will progress to unresponsiveness, diabetic coma, and, eventually, death. However, patients in DKA are seldom deeply comatose; therefore, a totally unresponsive patient likely has another problem, such as head injury, stroke, or drug overdose.

Signs and Symptoms of Hypoglycemia Versus Hyperglycemia

The signs and symptoms of hypoglycemia and hyperglycemia can be similar (**TABLE 21-2**). The signs and symptoms of simple hyperglycemia are usually mild, if present at all. They can include blurred vision, polyuria, polydipsia, polyphagia, orthostatic syncope, frequent infections, and skin ulcerations. If you encounter a patient with simple hyperglycemia who has not progressed to a more serious syndrome, treatment should include supportive care and transport.

Hyperglycemia usually progresses slowly, over a period of 12 to 48 hours, with the patient's level of consciousness deteriorating only gradually.

TABLE 21-2 Comparison of Hypoglycemia and Hyperglycemia

	Hypoglycemia	Hyperglycemia: Diabetic Ketoacidosis^a	Hyperglycemia: HHNS^b
Food intake	Insufficient	Excessive	Excessive
Insulin dosage	Excessive	Insufficient	Insufficient
Onset	Rapid, within minutes	Gradual—hours to days	Gradual—days to weeks
Skin	Pale to moist	Warm and dry	Warm and dry
Infection	Uncommon	Common	Usual
Thirst	Absent	Intense	Very intense
Hunger	Intense	Excessive	Excessive
Vomiting	Uncommon	Common	Uncommon
Breathing/ cardiopulmonary	Normal or rapid	Rapid, deep (Kussmaul respirations)	Tachycardia
Odor of breath	Normal	Sweet, fruity (nail polish remover/acetone smell)	No ketone body produced; therefore, there is no fruity odor
Blood pressure	Low	Normal to low	Hypotension
Pulse	Rapid, weak	Normal or rapid and full	Rapid, weak
Level of consciousness	Irritability, confusion, seizure, or coma	Restless merging to coma	Restless merging to coma
Urine: Sugar	Absent	Present	Present
Urine: Acetone	Absent	Present	Absent
Blood glucose level (mg/dL)	<60	>250	>600
Response to treatment	Immediately after administration of glucose	Gradual, within 6 to 12 hours following medical treatment	

Abbreviation: HHNS, hyperosmolar hyperglycemic nonketotic syndrome

^a Usually associated with type 1 diabetes

^b Usually associated with type 2 diabetes

© Jones & Bartlett Learning.

The load of glucose present within the kidneys during hyperglycemia results in glucose spilling into the urine, causing the body to become hyperosmotic. As the kidneys remove excess glucose, water is removed via increased urination, resulting in dehydration. The kidneys also help clear ketone bodies from the blood. As part of the substantial amount of water lost through diuresis, patients lose excessive amounts of sodium, potassium, and phosphates in the urine. As mentioned, this combination of effects results in both dehydration

and metabolic acidosis with associated electrolyte imbalances.

As a result of this process, the patient may present with the following signs and symptoms:

- Polyuria (excessive urine output), because of osmotic diuresis
- Polydipsia (excessive thirst), because of dehydration
- Polyphagia (excessive eating), probably related to inefficient use of nutrients

- Nausea and vomiting, the latter worsening the patient's dehydration
- Tachycardia as a consequence of dehydration
- Deep, rapid respirations (**Kussmaul respirations**)—the body's attempt to compensate for acidosis by blowing off carbon dioxide (CO_2)
- Warm, dry skin and dry mucous membranes, also reflecting dehydration
- Fruity odor of ketones (acetone smell) on the breath
- Abdominal pain
- Sometimes fever

Patients usually appear thin or dehydrated and have warm, dry skin. Patients also may exhibit orthostatic hypotension, supine hypotension, fatigue, altered mental status, and, with time, weight loss from the hypermetabolic state.

The respiratory rate is usually elevated and the tidal volume is increased (Kussmaul respirations) because of **ketonemia** (excess amounts of ketone bodies in the blood), acidosis, and the body's attempt to relieve itself of the excessive burden of CO_2 . These respiratory changes result in hypocapnia, which is recognized by lower than normal end-tidal CO_2 (ETCO_2) levels. Because ETCO_2 levels are affected, capnography is another tool you can use to confirm your diagnosis. DKA results in both Kussmaul respirations and metabolic acidosis; an ETCO_2 value less than 25 mm Hg corroborates your suspicions.¹⁷

In patients with type 2 diabetes, DKA is rare because insulin is still present, at least early in the course of the disease. Despite the elevated blood glucose levels, the level of insulin is sufficient to prevent uncontrolled breakdown of glycogen, adipose tissue, and muscle. In all patients with type 2 diabetes, regardless of the duration of the disease, ketone bodies can be found in the urine when the patient experiences hyperglycemia. With increased duration of type 2 diabetes, a loss of pancreatic insulin production may occur. In fact, patients can develop elevated serum ketone levels, reduced blood pH levels, and DKA similar to those patients with type 1 diabetes.

Hyperosmolar Hyperglycemic Nonketotic Syndrome

HHNS, formerly referred to as hyperosmolar nonketotic coma (HONK), is a metabolic derangement that occurs principally in patients with type

2 diabetes.¹⁸⁻²¹ This condition is characterized by hyperglycemia, hyperosmolarity, and an absence of substantial ketosis. The term *hyperosmolarity* describes highly concentrated blood as a result of relative dehydration. Key signs and symptoms of HHNS include the following:

- Hyperglycemia
- Altered mental status, drowsiness, and lethargy
- Severe dehydration, thirst, and dark urine
- Visual or sensory deficits
- Partial paralysis or muscle weakness
- Seizures

Oddly enough, fewer than 20% of patients present with a decreased level of consciousness.²² Instead, most patients have severe dehydration and focal or global neurologic deficits. In addition, AMI is frequently associated with HHNS. The clinical features of HHNS and DKA tend to overlap and are often observed simultaneously.

HHNS often develops in patients with diabetes who have a secondary illness that results in reduced fluid intake. Although infection (in particular, pneumonia and urinary tract infection) is the most common cause, many other conditions can cause

Words of Wisdom

Certain medications—including diuretic medications, beta-blockers, histamine-2 (H_2) blockers, dialysis, total parenteral nutrition, and dextrose-containing fluids—may contribute to the development of HHNS by increasing serum glucose levels, inhibiting insulin, or causing dehydration. Hyperglycemia and hyperosmolarity lead to osmotic diuresis and an osmotic shift of fluid to the intravascular space, resulting in further intracellular dehydration.

Words of Wisdom

There is no predictable correlation between the increase in a patient's blood glucose level and the degree of ketoacidosis in the blood. Not all patients with increased blood glucose levels have DKA or HHNS. Many people have glucose intolerance and hyperglycemia with absolutely no symptoms. Rely on the patient's clinical presentation rather than the "number."

TABLE 21-3 Comparison of Hyperglycemic Conditions

	Hyperosmolar Hyperglycemic Nonketotic Syndrome	Diabetic Ketoacidosis
Glucose	>600 mg/dL	>250 mg/dL
Arterial pH	>7.3	<7.3
Ketone bodies	Absent	Present
Type of diabetes mellitus	Type 2	Type 1

© Jones & Bartlett Learning.

altered mentation or dehydration. In most cases, the secondary illness is not identified.

Unlike patients with DKA, patients with HHNS do not experience ketoacidosis. The onset of DKA can occur in as little as a few hours, whereas HHNS can take up to weeks to develop. Blood glucose levels tend to be substantially higher in HHNS as compared with DKA (**TABLE 21-3**). Although most patients diagnosed as having HHNS have a known history of diabetes (usually type 2), as many as 20% do not have a prior diagnosis of diabetes.²³ The stress response to any acute illness tends to

increase hormones that favor elevated glucose levels: cortisol, catecholamines (epinephrine and norepinephrine), glucagon, and many other hormones have effects that tend to counter those of insulin. Various neurologic changes may be noted, including drowsiness and lethargy, delirium and coma, focal or generalized seizures, visual disturbances, hemiparesis, and sensory deficits.

Patient Assessment of Endocrine Emergencies

Assessment of a patient with a history of diabetes will be similar to your assessment of any other medical patient. Keep in mind that, in addition to hyperglycemic and hypoglycemic crises, patients with diabetes may have silent, or painless, heart attacks. A patient's only symptom may be "not feeling so well." This is especially true of geriatric patients. It is imperative to maintain a high index of suspicion and treat patients aggressively.

Special Populations

Diabetes in children may pose a particular management problem. First, the high levels of activity of children mean that they can use up circulating glucose more quickly than adults do, even after a normal insulin injection. Second, they do not always eat correctly and on schedule. Third, they have limited stores of liver glycogen that can be rapidly depleted. As a result, hypoglycemic crisis can develop more rapidly and more severely in children than in adults.

Street Smarts

Occasionally, patients with hypoglycemia or hyperglycemia are thought to be intoxicated, especially if their condition has caused a motor vehicle crash or other incident. Confined by police in a "drunk tank," a patient with diabetes is at risk. In such situations, an emergency medical identification bracelet, necklace, or card may help to save the patient's life. Often, only a blood glucose test performed at the scene or in the emergency department will identify the actual problem.

Certainly, diabetes and alcoholism can coexist in a patient. But you must be alert to the similarity in symptoms of acute alcohol intoxication and diabetic emergencies. Likewise, hypoglycemia and a head injury can coexist, and you must appreciate the potential even when the head injury is obvious.

Safety

When managing problems related to diabetes and altered mental status, exposure to body fluids is generally extremely limited. Follow standard precautions, as you would with any other patient. Always use gloves, and wash your hands carefully after obtaining and checking a blood sample or if you perform airway techniques.

Also, remain aware that patients with diabetic emergencies can become confused, and possibly aggressive or dangerous.

Scene Size-up

Evaluate scene safety as you arrive on scene and as you approach the patient. Make sure that all hazards are addressed. Remember that diabetic patients often use syringes to administer insulin. It is possible you may be stuck by a used needle that was not disposed of properly. Insulin syringes on the nightstand, insulin bottles in the refrigerator, a plate of food, or a glass of orange juice are important clues that may help you decide what is possibly wrong with your patient. Evaluate each situation quickly and make sure the necessary personal protective equipment is readily available. Standard precautions should consist of gloves and eye protection at a minimum.

As you approach, question bystanders on events leading up to your arrival. Determine whether this is your only patient and whether trauma was involved. Decide whether you will need any additional resources. Do not let your guard down even on what appears to be a routine call.

Primary Survey

Perform a rapid scan of the patient to form a general impression. How does the patient look? Does the patient appear anxious, restless, or listless? Is the patient

apathetic or irritable? Is the patient interacting with the environment appropriately? These initial observations may lead you to suspect high or low blood glucose values. In patients with altered mental status, suspect a low blood glucose level. Remember that hypoglycemia is a potentially life-threatening event.

Identify life threats, and provide life-saving interventions, particularly airway management. Determine the patient's level of consciousness using the AVPU (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive) scale. An unresponsive patient may have undiagnosed diabetes. Perform cervical spine immobilization, when indicated, and provide rapid transport. At the emergency department, diabetes and its complications can be quickly diagnosed.

As you are forming your general impression, assess the patient's airway and breathing. Patients showing signs of inadequate breathing, an altered mental status, or oxygen saturation (SpO_2) of 94% or less should receive high-flow oxygen at 12 to 15 L/min via nonrebreathing mask or ventilations via bag-mask device. A patient who is hyperglycemic may have rapid, deep respirations (Kussmaul respirations) and a sweet, fruity breath odor. A patient who is hypoglycemic will have normal or shallow to rapid respirations. If the patient is not breathing or is having difficulty breathing, open the airway, insert an

YOU are the Provider

Part 3

After reconfirming that the IV line is patent, you slowly administer 25 g of D_{50} over 4 minutes, per your protocols. As you are completing a bolus of D_{50} , the patient begins to moan and move around. You begin to reassess the patient. Approximately 5 minutes after the dextrose has been infused, the patient is able to communicate appropriately. According to his wife, he is now acting normally. You inform the patient of what you believe has happened, and state that he should be transported to the local emergency department for evaluation. The patient states, "I don't need to go to the hospital, my insulin pump should keep my sugar up."

Recording Time: 8 Minutes

Respirations	18 breaths/min
Pulse	Strong and regular, at 77 beats/min
Skin	Warm and dry
Blood pressure	154/88 mm Hg
Oxygen saturation (SpO_2)	100% at 15 L/min via nonrebreathing mask
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Does this patient require transport to the emergency department?

airway adjunct, and assist ventilations. Continue to monitor the airway as you provide care. Consider calling for paramedic backup if the patient needs a definitive airway.

If the patient is unresponsive, treat the person as any other unresponsive patient, with attention to the airway. If dextrose is indicated, use of an advanced airway should be avoided until dextrose has been administered. If the patient remains unresponsive, an advanced airway can be considered.

Patients with altered mental status, particularly those who are difficult to awaken, are at risk for losing their gag reflex. When the gag reflex is absent, patients cannot reject foreign materials in their mouth (including vomit), and their tongue will often relax and obstruct the airway. Therefore, you must carefully monitor the airway in patients with hypoglycemia, hyperglycemic crisis, or other complications such as stroke or seizure. Place the patient in a lateral recumbent position and have suction readily available.

After you have assessed airway and breathing and have performed the necessary life-saving interventions, check the patient's circulatory status. A patient with dry, warm skin indicates hyperglycemia, whereas a patient with moist, pale skin indicates hypoglycemia. The patient in hypoglycemic crisis will have a rapid, weak pulse.

Words of Wisdom

A patient with Kussmaul respirations may have an oxygen saturation of close to 100% because of their increased rate and depth of respirations. These patients still need high-flow oxygen via nonrebreathing mask. The respirations are in response to the increased acidosis in the body.

History Taking

Investigate the chief complaint or the history of the present illness. Responsive patients usually are able to provide their own medical history. If the patient has eaten but has not taken insulin, it is more likely that hyperglycemia is developing. If the patient has taken insulin but has not eaten, the problem is more likely to be hypoglycemia. A patient with diabetes will often know what is wrong. If the patient is not thinking or speaking clearly, or is unresponsive, attempt to obtain a medical history from family members or bystanders.

Physical signs such as tremors, diaphoresis, abdominal cramps, vomiting, a fruity breath odor, or a dry mouth may guide you in determining whether the patient is hypoglycemic or hyperglycemic.

You will need to obtain a SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) from your patient. In addition, be sure to ask the following questions of any ill patient who has a history of diabetes:

- Do you take insulin or any pills that lower your blood glucose?
- Have you taken your usual dose of insulin (or pills) today?
- Have you eaten normally today?
- Have you had any illnesses, unusual amount of activity, or stress today?

Also ask the patient or family about the following (these questions will help determine whether the patient is compliant with disease management):

- The patient's last meal and insulin dose
- Any vision changes, headaches, dizziness, or bleeding
- A recent change in the patient's bowel movements or eating habits
- Tingling, numbness, or swelling of the extremities. Patients with long-standing diabetes may have undergone amputation, and their residual limb may become infected or septic.

When you are assessing a patient who might have diabetes, check to see whether the patient has an emergency medical identification device (such as a wallet card, necklace, or bracelet) or ask the patient or a family member. Remember that the environment, bystanders, and medical identification devices may provide important clues about your patient's condition.

Special Populations

Be aware of the possibility of diabetes complicating a pregnancy. If you encounter a woman who is pregnant with an altered mental status, be sure to check her blood glucose level. If hypoglycemia is present, administer 25 g of D₅₀ IV. If hyperglycemia or DKA is present, isotonic crystalloid fluid boluses may be necessary to treat the associated dehydration.

Secondary Assessment

If time allows, conduct a secondary assessment.

Assess unresponsive patients with a full-body exam, looking for clues to their condition. With unresponsive patients or patients with an altered mental status, you must look for problems or injuries that are not obvious because the patient is unable to communicate these to you. Although an altered mental status may be caused by a blood glucose level that is too high or too low, the patient may have sustained trauma resulting from dizziness or from changes in level of consciousness, or may have another metabolic problem. An altered mental status may also be caused by something else, such as intoxication, poisoning, or a head injury. Also, because patients may have an altered perception of pain, particularly in their extremities, it is important to assess for any signs of sores or infections. A systematic examination of the patient may provide you with information essential to proper patient care.

When you suspect a diabetes-related problem, a secondary assessment should focus on the patient's mental status and ability to swallow and protect the airway. Obtain a Glasgow Coma Scale score to track the patient's neurologic status.

Obtain a complete set of vital signs. Pulse and respiratory rates will vary, depending on the diabetic emergency the patient is experiencing; at times, the blood pressure may be low as a result of dehydration from polyuria. It should be easier for you to identify abnormal vital signs when you know the blood glucose level is too high or too low. Remember, the patient may have abnormal vital signs and a normal blood glucose value. In this case, something else may be causing the patient's symptoms.

It is important to always obtain a blood glucose level in any patient with an altered mental status (**FIGURE 21-9**). Glucometers measure the glucose level in whole blood using either capillary or venous samples. For more information on treating patients with altered mental status, see Chapter 10, *Patient Assessment*.

It is important to read and understand the operator's manual before use because the specifications of the device may vary depending on the manufacturer. Some glucometers indicate low (Lo) when they detect a glucose reading of less than 20 mg/dL, whereas others display Lo when they detect a

FIGURE 21-9 Obtain the blood glucose level in any patient with an altered mental status.

Courtesy of Rhonda Hunt.

reading of less than 30 mg/dL. Conversely, the same is true with a high (Hi) reading; some glucometers read Hi at 550 mg/dL and some at 600 mg/dL; therefore, it is important to know both the upper and lower ranges at which your glucometer functions.

As mentioned earlier, the normal range for glucose levels in blood in nonfasting adults and children is 80 to 120 mg/dL; the blood glucose level in neonates should be higher than 80 mg/dL.

Reassessment

It is important to reassess the diabetic patient frequently to assess changes. Is there an improvement in the patient's mental status? Are the ABCs (airway, breathing, and circulation) still intact? Monitor the airway carefully and be alert for potential vomiting, especially if glucose has been administered orally. When patients who are hypoglycemic are given large quantities of glucose orally, they tend to become nauseated.

How is the patient responding to the interventions performed? How must you adjust or change the interventions? In many patients with diabetes, you will note marked improvement with appropriate treatment. Document each assessment, your findings, the time of the interventions, and any changes in the patient's condition. Base your administration of glucose on serial readings. The administration of glucose, glucagon, and IV fluids will be based on your service's protocols and standing orders.

Keep hospital personnel informed about the patient's history, the present situation, assessment findings, and your interventions and their results.

Emergency Medical Care of Endocrine Emergencies

General Management

When you are treating the patient, place the person in a position of comfort. If the patient has an altered mental status, establish an IV line with 0.9% normal saline or a saline lock. Measure the blood glucose level immediately and initiate treatment if the reading is less than 60 mg/dL and the patient is symptomatic. Give 12.5 to 25 g of dextrose in a concentration consistent with your local protocols (eg, D₅₀: 25 g of dextrose per every 50 mL, or 50% concentration); this dose will reverse most cases of hypoglycemia. Some EMS systems no longer carry D₅₀ and may use D₂₅ (25% dextrose concentration), D₁₀ (10% dextrose concentration), or glucagon. Glucagon is administered 1 mg intramuscularly (IM) or nasally, with a greatly increased recovery time as compared with IV D₅₀, D₂₅, or D₁₀. D₂₅ and D₁₀ are less concentrated and less hypertonic. The decreased osmolarity in these concentrations is less caustic to the veins and tissues. They also cause less fluctuation in blood glucose levels after administration. For these reasons, many agencies are moving to one or more of the dilute solutions rather than using D₅₀.

If the patient's condition does not improve after a dose of dextrose, and if you have reason to suspect a narcotic overdose (based on signs of pinpoint pupils, needle tracks, and/or depressed respirations), consider administering naloxone (Narcan).

Transport the unresponsive patient supine or in the lateral recumbent or recovery position (unless any injuries preclude that position). If there are indications of increasing intracranial pressure such as the Cushing reflex (slowing pulse, rising blood

pressure, and an erratic respiratory pattern), posturing, or unequal pupils, transport with the head elevated to a 30° to 45° angle and the head midline to assist in venous return and minimize intracranial pressure. Always keep the mouth and pharynx suctioned free of secretions, vomitus, and blood.

Management of Hypoglycemia

Hypoglycemic patients may experience permanent cerebral damage if blood glucose levels are not restored rapidly. Management of hypoglycemia includes immediately increasing blood glucose levels, with the precise treatment depending on several factors. It is always preferable to provide the least-invasive method of treatment possible that will successfully address the condition.

If the hypoglycemic patient is alert and able to swallow without the risk of aspiration, administer sugar by mouth. Provide juice sweetened with sugar, a candy bar, or any item that contains sugar. Do not be afraid to give too much sugar. Do not give sugar-free drinks that are sweetened with saccharin

Words of Wisdom

When you are unable to measure a patient's glucose level and are unsure whether the patient is hypoglycemic or hyperglycemic, always err on the side of caution and give glucose. More glucose in a hyperglycemic patient will not cause harm, but it may save the life of a hypoglycemic patient, especially if the patient is in hypoglycemic crisis.

One exception to this is the potential for a head injury. If the patient has a mechanism of injury that may lead you to suspect a head injury, do not administer glucose. Instead, focus on oxygenation and provide rapid transport.

If you are treating an older adult or a patient whose clinical history suggests that the problem may be stroke, note that it is especially important to measure the patient's blood glucose level prior to administration of dextrose. Administration of concentrated glucose solutions in a situation of suspected stroke may exacerbate cerebral damage.

Situations in which you are unable to measure a patient's blood glucose level should be extremely rare, particularly if you are diligent about checking all of your equipment, including your glucometer, prior to every shift.

Words of Wisdom

Fluids and dextrose solutions may also be given through an IO (intraosseous) line. However, IO access is usually reserved for critical situations where IV access cannot be obtained.

or other synthetic sweetening compounds because they will have little or no effect. Oral glucose may also be given, but most patients prefer the taste of *regular* food or drink as opposed to the taste of oral glucose and will be more cooperative.

The first-line medical treatment for patients with hypoglycemia is to administer oral glucose as discussed in the next section, assuming the patient is responsive and there is no risk of aspiration. If this is not possible, you should administer dextrose via the IV route. Finally, if IV access cannot be obtained, you should administer glucagon via the IM route.

Administering Oral Glucose

Oral glucose is commercially available in tablet and gel forms that dissolve when placed in the mouth (**FIGURE 21-10**). Trade names for the gel include Glutose and Insta-Glucose. The only contraindications to glucose are an inability to swallow or unresponsiveness because aspiration (inhalation of the substance) can occur. Oral glucose itself has no side effects if it is administered properly; however, aspiration in a patient who does not have a gag reflex can have lethal results.

If your hypoglycemic patient is unresponsive, or if there is any risk of aspiration, do not give anything by mouth! Although patients with hypoglycemia and altered mental status need glucose, *never give anything by mouth to an unresponsive patient*, even if you suspect hypoglycemic crisis. Instead, administer IV/IO glucose or IM glucagon.

Street Smarts

A tube of commercially prepared cake icing is an excellent substitute for oral glucose. You may be able to find some in the patient's kitchen.

FIGURE 21-10 Oral glucose is commercially available in gel and tablet form. One tube of gel equals one dose.

Reproduced with permission from Perrigo Company plc.

A patient who is alert can self-administer the glucose gel or tablets. For those who need assistance, the gel can be squeezed into the open mouth in small increments to allow time to swallow. Have water available—the gel is extremely sweet and viscous. Another option is to place the gel on a tongue depressor and place it between the patient's cheek and gum for absorption with the gel side turned toward the cheek. The patient will usually become more alert within minutes.

Reassess the patient frequently after administering glucose, even if you see rapid improvement in the patient's condition. Remain alert for airway problems, sudden loss of consciousness, or seizures. Provide prompt transport to the hospital; do not delay transport just to give additional oral glucose if the patient has an altered mental status.

When there is any doubt about whether a responsive patient with diabetes is going into hypoglycemic or hyperglycemic crisis, most protocols will err on the side of giving glucose. The risk of increasing the glucose level of a patient who is already hyperglycemic is minimal compared with the benefit of increasing the glucose level of one who is hypoglycemic. Hypoglycemia is detrimental to the patient's overall health and can quickly result in other systemic problems. The patient with diabetes who is unresponsive and having seizures is more likely to be in a hypoglycemic crisis. When in doubt, consult medical control.

For patients presenting with signs of dehydration, administer a 20-mL/kg bolus of an isotonic crystalloid solution such as normal saline or lactated Ringer solution. Treatment is aimed at rehydrating the patient and providing prompt transport to an appropriate facility. Reassess the patient after the initial bolus and repeat if needed. Reassure the patient en route and provide general comfort measures.

Administering IV Dextrose

If the hypoglycemic patient has an altered mental status or is unable to swallow, you will need to administer IV dextrose.

Exercise caution when using dextrose; contraindications include the presence of increased intracranial pressure or possible intracranial bleeding. When the unresponsive patient is older than 55 years or the family gives a history of recent transient ischemic attacks or stroke, assess glucose levels to rule out hypoglycemia prior to administering IV dextrose.

Also use caution with patients suspected of having hypokalemia (low potassium levels), such as patients who are taking diuretics. Administering glucose in the presence of hypokalemia worsens the effects of low potassium. However, the potential for worsening the patient's hypokalemia should not be a factor when dealing with a severely hypoglycemic patient.

Dextrose comes packaged in various concentrations. D₅₀ is 25 g in 50 mL, D₂₅ is 25 g in 100 mL, and D₁₀ is 25 g in 250 mL. The total dose of dextrose in these formats is the same, though the concentration and volumes differ.

Doses of dextrose are as follows. D₅₀ is usually supplied in a prefilled syringe containing 25 g of dextrose dissolved in 50 mL of water.

- **Adults:** 12.5 to 25 g (50 mL) of D₅₀ (or follow local protocol)
- **Children 1 year and older:** 0.5 to 1 g/kg per dose of D₂₅ or D₁₀ via slow IV push. (Empty one-half of the syringe of D₅₀ and draw up normal saline to fill the tube; this will give a concentration of 25% if your service does not carry the prefilled syringes of D₂₅.)
- **Neonates and infants:** 200 to 500 mg/kg of D₁₀ solution via slow IV push. (Put 2 mL of D₅₀ into a syringe and add 8 mL of normal saline.)

Dextrose may cause serious damage to tissue from extravasation outside the vein. Therefore, you must give dextrose by IV push while carefully monitoring for infiltration into local tissue.

The steps for administering dextrose to a patient with an altered level of consciousness are summarized here:

1. Insert an IV line with the largest catheter possible for the patient and in the largest possible vein.
2. Attach an IV bag of an isotonic crystalloid solution such as 0.9% normal saline. Check the IV line carefully to confirm that it is patent and flowing freely. Inject a test bolus of 10 to 20 mL of normal saline, making sure the IV line is not susceptible to infiltration. Recheck the status of the line by lowering the IV bag and looking for backflow of blood into the infusion set.
3. After you are certain the IV line is reliable, open the line wide, crimp the line superior to the administration port, and administer 12.5 to 25 g (25 to 50 mL) of dextrose slowly, over at

least 3 minutes. Depress the plunger slowly to avoid rupturing the vein.

When administering D₅₀, to ensure patency of the line, draw back on the prefilled syringe to observe a blood return. Keep in mind that D₅₀ can also be given IO or rectally.

4. Recheck after one-half of the dose has been given by pulling back on the plunger again to check for blood return. Flush the IV line by opening the line for a few seconds. If the cause of unresponsiveness is hypoglycemia, the patient will often quickly awaken—although in cases of severe hypoglycemia, another 25 g of D₅₀ may be required to restore a normal level of consciousness.

The steps for performing IV infusion are covered in greater detail in Chapter 13, *Vascular Access and Medication Administration*.

Administering Glucagon

Administering glucagon IM is an option when IV access (for administering dextrose) cannot be obtained in a hypoglycemic patient. However, it is important to remember that glucagon is only effective when there are stores of glycogen to draw from. If glycogen stores are depleted, glucagon will be ineffective.

Glucagon is supplied in 1-mg ampules and requires reconstitution with the provided diluent (**FIGURE 21-11**). The dosage for an adult is 1 mg IM and may be repeated in 7 to 10 minutes. The pediatric dosage is 0.5 mg or 20 to 30 mcg/kg IM for children who weigh less than 20 kg (44 lb). For children weighing greater than 20 kg, the dose is the same as for adults.^{24,25}

FIGURE 21-11 Glucagon is supplied in 1-mg ampules and requires reconstitution.

© dpa picture alliance archive/Alamy Stock Photo.

Glucagon should be used in conjunction with dextrose whenever possible. If the patient does not respond to the second dose of glucagon, dextrose must be administered. Review Chapter 13, *Vascular Access and Medication Administration*, for the steps to administer a medication via the IM route.

Words of Wisdom

Glucagon can also be administered intranasally and is supplied as a powder in a prefilled autoinjector for home use. In the prehospital environment, reconstitute 2 mg of glucagon (2 vials) in a total volume of 1 mL of diluent (0.5 mL per vial), and load the solution into a syringe with an atomizer attached.²⁶ Insert the atomizer into one nostril and briskly depress the plunger to deliver half of the solution, then repeat with the remaining glucagon in the other nostril. Remember to always obtain permission from medical control and to follow local protocols.

Management of Hyperglycemia and DKA

Patients with DKA will generally present with a markedly elevated glucose level and signs and symptoms consistent with severe hyperglycemia; if your field measurement of the patient's glucose level is more than 250 mg/dL, the physician will probably order treatment for DKA. The goals of prehospital treatment of DKA are to begin rehydration and to correct the patient's electrolyte and acid-base abnormalities. Specific treatment with insulin will occur on the patient's arrival at the hospital, where therapy can be closely monitored with laboratory determinations of blood glucose levels, ketones, and other values.

Maintain the patient's airway and administer oxygen. Be particularly alert for vomiting, and have suction ready. Consider paramedic backup for definitive airway control if needed. Gain IV access and administer a 20-mL/kg bolus of an isotonic crystalloid solution for signs of dehydration or if the patient is hypotensive. Reassess and provide additional boluses as needed.

Hyperglycemic patients who have not reached the stage of DKA may not need large quantities of fluid. Treat the patient symptomatically, providing oxygen and IV fluid as needed.

Management of HHNS

The treatment of HHNS in the prehospital setting follows the pathway for dehydration and altered mental status. Airway management is the top priority because the unresponsive patient often is unable to maintain and protect the airway. For this reason, advanced airway management may be indicated and should be completed as early as possible. Cervical spine immobilization should be considered for all unresponsive patients with a possible mechanism of high-energy injury. Obtain a blood glucose level as soon as possible. Large-bore IV access (18 gauge) should be gained as soon as possible.

After you have initiated the IV line, a bolus of 500 mL of 0.9% normal saline is appropriate for almost all adults who are clinically dehydrated. In patients with a history of heart failure and/or renal insufficiency, give fluid sparingly (250 mL may be a more appropriate starting point) while monitoring breath sounds for developing pulmonary edema. Fluid deficits in patients with HHNS may amount to 10 L or more. These patients may receive 1 to 2 L within the first hour. You may also need to treat for hypoglycemia if glucose levels are low and the patient is symptomatic.

Assessment Pearls

- After managing the airway, immediately assess glucose levels in any patient with an altered mental status.
- Educate patients about the signs and symptoms of diabetes and the importance of maintaining glucose levels within a normal range.
- Hyperglycemic patients need insulin. Administer IV fluid for rehydration as needed and provide prompt transport.
- Endocrine and hematologic issues tend to be chronic. When obtaining patient history, question the patient about previous episodes. How is this one the same or different?
- Most hematologic emergencies result in a decrease in oxygenation. Pay particular attention to patient presentation.
- Pulse oximeters may not read accurately in the presence of hematologic emergencies. Treat the patient, not the diagnostic tool!

Hematologic Emergencies

Hematology is, by definition, simply the study of blood; however, the specialty addresses not only the blood, but also the ways in which its constituent parts are involved in health and disease. These components include **red blood cells (RBCs)**, **white blood cells (WBCs)**, platelets, and individual proteins involved in the bleeding and clotting cascades, as well as the **hematopoietic system**—that is, organs and tissues involved in the production of blood components (primarily bone marrow, spleen, and lymph nodes). Most EMS systems rarely respond to hematologic emergencies.

The blanket term **hematologic disorder** refers to any disorder of the blood. Within this general category, **hemolytic disorders** refer to disease processes that cause the breakdown of RBCs, and **hemostatic disorders** refer to bleeding and clotting abnormalities. These disorders can be complex, difficult to assess, and challenging to treat in the prehospital setting.

As an AEMT, you should have a basic understanding of the hematopoietic system and hematologic disorders, and know how to respond to these kinds of emergencies appropriately. Although you may be able to provide only limited interventions

in the field for patients with hematologic disorders, your actions may not just offer support, but can save the patient's life.

Anatomy and Physiology Review: Hematology Blood and Plasma

Without blood, we would not be able to live. Blood performs the following functions:

- **Respiratory function.** Transports oxygen from the lungs to the tissues and carbon dioxide from the tissues to the lungs
- **Nutritional function.** Carries nutrients (glucose, proteins, and fats) from the digestive tract to cells throughout the body
- **Excretory function.** Ferries the waste products of metabolism from the cells where they are produced to the excretory organs
- **Regulatory function.** Transports hormones to their target organs and transmits excess internal heat to the surface of the body to be dissipated
- **Defensive function.** Carries defensive cells and antibodies, which protect the body against foreign organisms

YOU are the Provider

Part 4

You inform the patient that you believe that his insulin pump is not functioning correctly and that he should be evaluated in the emergency department. The patient again states that he does not wish to be transported, but you are able to persuade him to speak with your medical control physician. You proceed to contact online medical control and explain the situation to the physician, who readily agrees with you that the patient should be evaluated and asks to speak with the patient. After approximately 2 minutes, the patient agrees to transport, and you thank the medical control physician for his assistance. You assist the patient onto the stretcher and begin transport to the hospital. En route, you continue administering high-flow oxygen, ensure that the IV line is still patent, and recheck the patient's blood glucose level, which is found to be 189 mg/dL. On arrival at the emergency department, you turn over care to the awaiting nurse; the patient thanks you for your prompt treatment.

Recording Time: 16 Minutes

Respirations	20 breaths/min
Pulse	Strong and regular, at 68 beats/min
Skin	Warm and dry
Blood pressure	154/78 mm Hg
Oxygen saturation (SpO₂)	100% at 15 L/min via nonrebreathing mask
Pupils	PERRLA

8. Why is it important to reassess the patient's blood glucose level during transport?

Blood is made up of two main components: plasma and formed elements (cells). **Plasma**, a straw-colored fluid, is essentially 92% water and 6% to 7% proteins; the remainder consists of a variety of other elements (including electrolytes, clotting factors, and glucose). Plasma accounts for 55% of the total blood volume. All formed element components (RBCs, WBCs, and platelets) are transported through the body in plasma.

Most of the formed elements (99%) are RBCs (erythrocytes). Within the RBCs, iron-rich hemoglobin is responsible for carrying oxygen to the tissues. RBC production occurs within a **stem cell**, a type of cell that develops into other types of cells in the body. The production of RBCs is stimulated by a protein secreted by the kidneys in response to circulatory need. RBCs may take as long as 5 days to mature and have an average life of approximately 4 months. Oxygen attached to hemoglobin gives blood its characteristic red color, although many other factors can change the color of blood (such as carbon monoxide poisoning).

WBCs (leukocytes) are larger than RBCs and are also found in the bloodstream. They provide the body with immunity against “foreign invaders,” fighting infection and removing dead cells. WBCs are derived from stem cells. Several types of WBCs exist, each of which performs a specific task in relation to maintaining the immune system.

Platelets (thrombocytes) are the smallest of the formed elements and are responsible for clot formation. Approximately two-thirds of the body’s platelets circulate throughout the blood; the rest are stored in the spleen. Platelets are also derived from stem cells. They have an average life span of approximately 7 to 10 days. When damage occurs to a blood vessel, platelets are sent to the site of injury to help create a blood clot to stop the bleeding.

Platelets form the initial plug following vascular injury; the clotting proteins then toughen and complete the blood clot. Without platelets, our bodies would not be able to stop bleeding. However, there can be too much of a good thing with platelets: conditions such as **thrombocytosis**, in which the body produces too many platelets, can result in other dangerous medical conditions, such as **thrombosis**, which is coagulation or clotting of blood inside of a blood vessel.

Words of Wisdom

Platelets form the initial plug following vascular injury. Clotting proteins then toughen and complete the blood clot.

Hemostasis is a highly complex process that allows the body to stop bleeding through vascular spasm, coagulation, and platelet plugging. The opposite of hemostasis is hemorrhage. Clots themselves are made up of fibrin. When injury is detected, thrombin converts fibrinogen to fibrin, and the clotting process begins. Calcium acts as a binding agent, holding fibrin fibers close together to form the meshwork of the clot.

Any process that interferes with the activation or continuation of the clotting cascade or hemostasis is known as a **coagulopathy**. Coagulopathies can result in heavy or prolonged bleeding. One such bleeding disorder is von Willebrand disease, in which the blood’s ability to clot is decreased because of the absence of a key protein, von Willebrand factor, that is necessary for platelet adhesion.

Words of Wisdom

In a normal adult, the WBC count initially increases in response to infection. As the infection continues, the WBC count may decrease as the WBCs are exhausted faster than they can regenerate. Thus, a low WBC count does not necessarily indicate absence of infection.

Blood-Forming Organs and RBC Production

Although many parts and organs of the human body can alter or affect the hematologic system, the major players are the bone marrow, liver, and spleen (**FIGURE 21-12**).

The bone marrow is the primary site for cell production within the human body. Bone marrow may be found in most of the long bones plus the pelvis, skull, and vertebrae.

The liver produces the **clotting factors** found in the blood. It filters the blood to remove toxins and is essential to normal metabolism and homeostasis. As old RBCs enter the liver, they are broken down into bilirubin, a protein that is excreted by the liver

FIGURE 21-12 The bone marrow, liver, and spleen are the main components of the body related to the hematologic system.

© Jones & Bartlett Learning.

within the bile. The liver is a highly vascular organ that also stores some blood within itself.

The spleen is also quite vascular. It is involved with the filtering and breakdown of RBCs, assists with the production of WBCs, and has an important role in providing homeostasis and infection control. The spleen stores approximately one-third of the body's platelets. If the spleen is removed, then the platelets formed after that time remain in the blood throughout their life span.

Blood Classifications

To ensure compatibility and prevent medical problems during blood component replacement, blood type classifications have been developed. The **ABO system** uses the RBC classification types O, A, B, and AB to indicate which antigens are found in the plasma membrane (**TABLE 21-4**). See Chapter 7, *The Human Body*, for more on the ABO system.

Blood contains a secondary antigen, known as the Rh antigen (the name signifies that the antigen was first found in the Rhesus monkey). In the United States, approximately 85% of all Americans have this antigen.²⁷ In blood types that are positive (for example, A+), the blood contains the Rh antigen.

Transfusion Reactions

Some patients may be receiving or may have previously received a blood transfusion. It is important to determine a patient's blood type and the type of blood received. When patients receive blood

TABLE 21-4 Blood Types

Blood Type	ABO Antigens	ABO Antibodies	Acceptable Blood Donor Types
A	A	Anti-B	A, O
B	B	Anti-A	B, O
AB	A, B	None	A, B, AB, O
O	None	Anti-A Anti-B	O

© Jones & Bartlett Learning.

or plasma that matches their classification (A+ into A+) or the universal donor blood type (O), problems rarely arise. However, if patients receive a blood type that is different than their own (for example, a patient with type A receives type B), a transfusion reaction will occur. Also, if a patient with A− blood receives an A+ transfusion, a transfusion reaction could occur, but this is rare. Blood reactions are similar to an anaphylactic reaction—they occur rapidly and can cause severe circulatory collapse and even death. High-flow oxygen should be administered. When a patient receives a blood transfusion, it is important to monitor the patient closely for the first 30 to 60 minutes because transfusion reactions typically begin within this time frame.

Pathophysiology of Hematologic Emergencies

Sickle Cell Disease

Sickle cell disease is, by far, the most common inherited blood disorder. Although it primarily affects African American, Puerto Rican, and European populations, it can occur in anyone. Approximately 100,000 people in the United States have sickle cell disease.²⁸ Mortality at younger ages is common; the average life expectancy is 42 years for men with sickle cell anemia and 48 years for women with this disorder.²⁹

Sickle cell disease starts with a genetic defect of the adult-type hemoglobin (HbA). Over the course of the disease, the RBCs may become rigid and deformed. The defective RBCs have an oblong shape

**A****B**

FIGURE 21-13 **A.** Normal red blood cells. **B.** Sickle cells.

A: © Sebastian Kaulitzki/Shutterstock; **B:** © Science Picture Co/Science Source.

instead of a smooth, round shape (**FIGURE 21-13**). This shape makes the RBC a poor oxygen carrier, which means a patient with this disease is highly susceptible to hypoxia. Since sickle cells also have a much shorter life span than normal erythrocytes, the patient is also more susceptible to develop anemia.

The odd shape may also cause RBCs to lodge in small blood vessels, resulting in thrombosis. Defective RBCs may migrate to the spleen, causing the organ to swell and rupture, which can result in death.

Sickle cell disease may result in an aplastic crisis, a hemolytic crisis, or thrombosis. In an aplastic crisis, the body temporarily stops RBC production, causing the patient to become easily tired, anemic, pale, and short of breath. In contrast, a hemolytic crisis arises when acute RBC destruction results in jaundice. In both cases, the patient may have rapidly evolving anemia, **leukocytosis**, and fever. The

odd shape of the RBCs may also cause these cells to become lodged in small blood vessels, resulting in thrombosis. A sickle cell crisis may manifest in several ways:

- A **vaso-occlusive crisis** results from blood flow to an organ becoming restricted, causing pain, ischemia, and often organ damage. Most vaso-occlusive crises last between 5 and 7 days. Frequently, circulation to the spleen becomes obstructed as a result of its narrow vessels and function of removing damaged RBCs. Vaso-occlusion in the brain may result in a CVA (stroke).
- **Acute chest syndrome** is a vaso-occlusive crisis that can be associated with pneumonia. Common signs and symptoms include chest pain, fever, and cough.
- An **aplastic crisis** is a worsening of the patient's baseline anemia (lack of circulating RBCs in the body), which causes tachycardia, pallor, and fatigue. This may be caused by the parvovirus B19, which affects the production of RBCs, almost stopping new production for 2 to 3 days.
- A **hemolytic crisis** is an acute accelerated drop in the patient's hemoglobin level. Caused by RBCs breaking down at a faster than normal rate, this type of crisis is common in patients with glucose-6-phosphate dehydrogenase deficiency (a common enzyme deficiency).
- A **splenic sequestration crisis** is caused by painful, acute enlargement of the spleen, causing the abdomen to become hard and bloated.

In acute crises, patients may have substantial pain resulting from congested vessels that do not allow for the passage of oxygen and nutrients into

Special Populations

Acute splenic sequestration syndrome is a life-threatening complication in which RBCs become trapped in the spleen, causing a dramatic decline in the amount of hemoglobin available in the circulation. Patients present not only with a painful, acute abdomen, but also with sudden weakness, pallor, tachypnea, and tachycardia. Acute splenic sequestration syndrome usually occurs in infants or toddlers.

Words of Wisdom

Patients with sickle cell disease may report multisystem involvement, including chest, abdominal, and arthritic-type pain, although some may report only fatigue or achiness along with fever. Pediatric patients will typically present with initial pain in the hands and feet, whereas adult patients will report back and proximal extremity pain.

tissues and joints. They may experience frequent infections, which can result in sepsis and death. Over time, various organs may be destroyed as circulation is impeded. Patients may often have signs of mild dehydration, splenomegaly, cardiomegaly, and many other complaints.

Patients with chronic sickle cell attacks are susceptible to severe, life-threatening complications of which you must be aware. Although some of these complications take days to weeks to develop, some complications are acute and life threatening. Some of the potential complications of sickle cell disease are as follows:

- Cerebrovascular attack
- Gallstones
- Jaundice
- Osteonecrosis
- Splenic infections
- Osteomyelitis (or septic arthritis)
- Opiate tolerance
- Leg ulcers
- Retinopathy
- Chronic pain
- Pulmonary hypertension
- Chronic renal failure

Anemia

Anemia is defined as a hemoglobin or RBC level that is lower than normal. Usually, this condition is associated with some type of underlying disease process. Anemia may also result from acute or chronic blood loss, or from a decrease in production or an increase in destruction of erythrocytes. Anemia may be an outcome of a preexisting hemolytic disorder (a disorder related to the breakdown of RBCs).

Iron-deficiency anemia is the most common type of anemia. Other typical causes include gastrointestinal blood loss, menstrual bleeding, and blood

loss as a result of frequent donations or diagnostic tests for patients hospitalized for long periods. In children, it is most often related to premature birth or low birth weight.

Anemia may sometimes be caused by an inherited hemolytic disorder, such as sickle cell disease or thalassemia. In these disorders, the RBCs over time, become rigid and deformed. The RBCs may then become lodged in small blood vessels, resulting in a thrombosis (blood clot).

Anemia may also be caused by hematologic disorders resulting from a deficiency of an enzyme known as glucose-6-phosphate dehydrogenase. This enzyme helps protect RBCs during infections. When levels of this enzyme are low, cells can become damaged. Although glucose-6-phosphate dehydrogenase deficiency is most commonly seen in African Americans, it can occur in people of any racial or ethnic group.

Another common type of acquired anemia develops when the flow of RBCs is disrupted owing to problems with blood vessel linings (such as aneurysms and weaknesses) or blood clots. In autoimmune disorders, RBCs are destroyed by the body's own antibodies, which erroneously perceive the normal blood cells as foreign invaders. RBCs can also be destroyed by microorganisms in the blood.

Anemia can also have serious consequences for people who travel to high-altitude areas. The combination of a smaller number of RBCs and the reduced partial pressure of oxygen in the atmosphere can result in serious conditions that a healthy person would not experience, such as hypoxia, difficulty breathing, and chest pain.

Your basic assessment should be the same for all patients, although you may want to ask some specific questions when anemia is suspected. Most commonly, patients with anemia will report feeling worn down, having no energy, or feeling as if they have overexerted themselves. Patients may also report that they "can't catch their breath." Owing to the reduction in their hemoglobin level, some may have angina-type chest pain related to decreased oxygen availability to the heart muscle. The reduction in functional RBCs can also result in pale skin. Subtle variations may be seen by assessing the conjunctiva of the eyes, the inside of the lips, and the creases of the palms of the hand. These areas can be instrumental in identifying pallor, especially in patients with darker skin. Other conditions that are common

in patients with anemia include **leukopenia** (reduction in WBCs) and **thrombocytopenia** (reduction in platelets); both conditions can induce more frequent infections, fevers, cutaneous bleeding, and nosebleeds.

Words of Wisdom

When abnormalities of the blood cells are suspected, note the following:

- Anemia commonly results in complaints of fatigue, lethargy, and dyspnea.
- Low WBC counts (leukopenia) often result in infection and fever.
- Low platelet counts (thrombocytopenia) often cause cutaneous bleeding (including petechiae) and bleeding from mucous membranes (such as nosebleeds and rectal bleeding).

Clotting Disorders

A clotting disorder is a condition in which there is an abnormality in the blood's clotting ability. The development of a blood clot is called thrombosis and can occur in either arterial or venous blood vessels. The patient's symptoms are related to the part of the vascular system in which the clot occurs, the size of the clot, and whether the clot becomes dislodged and travels to another part of the body.

Thrombophilia

Thrombophilia, or the tendency to develop blood clots, affects many people around the world.

Thrombosis is a common medical problem and may manifest itself as the formation of a blood clot in a blood vessel or in one of the chambers of the heart. Pulmonary emboli secondary to deep vein thromboses are a leading cause of death in hospitalized patients.

Many patients with thrombophilia receive anticoagulant medications that thin the blood, which helps decrease the tendency to form a clot. Examples of these medications include aspirin, heparin, and warfarin (Coumadin). Typically, pediatric patients do not experience blood clots.

The following are some risk factors for increased clotting:

- Recent surgery
- Impaired mobility

- Heart failure
- Cancer
- Respiratory failure
- Infectious diseases
- Age older than 40 years
- Being overweight/obesity
- Smoking
- Oral contraceptive use
- Recent trauma
- Recent long-distance travel (eg, multihour car or plane ride)

Hemophilia

Hemophilia is a genetic bleeding disorder in which clotting does not occur or occurs insufficiently (von Willebrand disease). In people with hemophilia, the body is not able to control bleeding by developing spontaneous clots as normal, resulting in an increased bleeding time. This condition occurs predominately in males, and the most common—hemophilia A—occurs in approximately 1 in every 5,000 male births.³⁰ The disease is classified into two primary types:

- **Hemophilia A.** The most common type, hemophilia A is a result of low levels of factor VIII.
- **Hemophilia B.** This second most common type is associated with a deficiency of factor IX.

The levels of factors VIII and IX determine the severity of the disease.

Both type A and type B have the same signs and symptoms. Acute and chronic bleeding can occur at any time and may or may not be life threatening. Any injury or illness that can cause bleeding should not be taken lightly in a person with hemophilia. Spontaneous intracranial bleeding is common in hemophilia and is a frequent cause of death in these patients. Patients with substantial acute bleeding episodes require hospitalization for transfusion and often require infusion of factors VIII or IX.

When you are obtaining the patient's history, you may learn that the patient has a history of conditions associated with hemophilia. In addition to managing the ABCs, be alert for signs of acute blood loss (pallor, weak pulse, and hypotension). Note any bleeding of unknown origin, such as nosebleeds, bloody sputum, and blood in the urine or stool (melena). Patients may exhibit signs of hypoxia owing to the reduction in oxygen-carrying capacity as a result of blood loss.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) may result from any number of life-threatening conditions, including massive injury and hypotension resulting from trauma. Sepsis and obstetric complications also may cause DIC.

This condition progresses in two stages. First, free thrombin and fibrin deposits in the blood increase, and platelets begin to aggregate. In this stage, defibrination, or a breakdown of the fibrin clots, occurs owing to excessive bleeding, massive blood loss, or tissue injury. Second, uncontrolled hemorrhage results from the severe reduction in clotting factors.

The mortality rate for patients with DIC is quite high, especially in acute cases; some studies have shown it to be 60% to 65%.³¹ The primary causes of death relate to uncontrolled bleeding, hypotension, and shock.

As you assess and care for critically injured or ill patients, keep in mind the issues that may result in DIC. Your goal is to identify signs and symptoms commonly associated with DIC or progression toward this coagulopathy. In cases involving severe trauma, patients may have episodes of respiratory difficulty, signs of shock, and skin changes ranging from cold and clammy, to pallor, to small black-and-blue marks (purpura) on the chest and abdomen.

Words of Wisdom

Patients with DIC experience simultaneous multiple organ failure (such as kidneys, lungs, and heart), accompanied by bleeding from IV sites, bleeding into joints, and, possibly, intracranial hemorrhage.

Patient Assessment of Hematologic Emergencies

Assessment of a patient suspected of having a hematologic disorder should be no different from assessment of any other patient, albeit with a few additional items to consider and questions to ask. Also, be supportive of the patients and their families; some patients with a blood disorder may not be

willing to disclose the condition because they may feel that they will be treated differently.

Scene Size-up

Although your report from dispatch may be for a patient with an unknown medical problem, most patients presenting with a sickle cell crisis have experienced a crisis before and will relay that information to the dispatcher. As always, ensure the scene is safe for entry, consider the mechanism of injury and/or nature of illness, determine the number of patients, and assess for hazards and the need for additional help. Standard precautions should consist of gloves and eye protection at a minimum. Remember to evaluate each situation quickly and make sure the necessary personal protective equipment is readily available.

Patients experiencing a vaso-occlusive crisis are often in extreme pain and would benefit from administration of analgesics. Call for paramedic backup early.

Primary Survey

An African American patient or any patient of Mediterranean descent who reports severe pain may have undiagnosed sickle cell disease.

Remember that even though a person has a history of sickle cell disease, sickle cell disease may not be causing the current problem; trauma or another type of medical emergency may be the cause. For this reason, you must always perform a thorough, careful primary survey, paying attention to the ABCs and immediately correcting any life-threatening issues.

Perform a rapid full-body scan of the patient to form an initial general impression of the patient. How does the patient look? Does the patient appear anxious, restless, or listless? Is the patient apathetic or irritable? Determine the patient's level of consciousness.

As you are forming your general impression, assess the patient's airway and breathing. Patients showing signs of inadequate breathing, an altered mental status, or SpO₂ of 94% or less should receive high-flow oxygen at 12 to 15 L/min via nonrebreathing mask or ventilation via bag-mask as needed. Should you need to provide

additional airway support with suctioning and/or basic or advanced airways, be aware that even minor trauma during these procedures can result in bleeding into the airway and increase the risk of airway compromise. A patient who is experiencing a sickle cell crisis may have increased respirations as a result of severe pain or exhibit signs of pneumonia. Continue to monitor the airway as you provide care.

After you have assessed the airway and breathing and have performed the necessary interventions, check the patient's circulatory status. An increased heart rate represents a compensatory mechanism by attempting to “force” the sickled cells through smaller vasculature. Look for signs of shock, such as a rapid pulse rate and low blood pressure. If you find any life-threatening conditions, take immediate steps to manage them and provide urgent transport to an appropriately equipped receiving facility.

In patients with suspected hemophilia, be alert for signs of acute blood loss such as pallor, weak pulse, and hypotension. Note any bleeding of unknown origin, such as nosebleeds, bloody sputum, and blood in the urine or stool. Patients with hemophilia may exhibit signs of hypoxia or shock because of blood loss. Fluid resuscitation may be necessary for these patients; however, it must be administered with care so as not to “wash out” the clots that are forming.

Whether you decide to rapidly transport the patient will depend on the severity of the patient's condition and the patient's wishes. Patients with a history of sickle cell disease, but who have not had a crisis in some time, may require emotional support and refuse transport. However, transport to an emergency department should always be recommended to any patient who is experiencing a sickle cell crisis or has a history of hemophilia and is bleeding.

History Taking

It is extremely important to understand the chief complaint; to do so, you may need to be inquisitive about the patient's history and SAMPLE history. When you are obtaining the patient's history, you may discover previous or current sickle cell disease or hemophilia conditions.

Responsive medical patients are usually able to provide their own medical history to help you identify a cause for their severe pain. Do not take a call for a person having a sickle cell crisis lightly. Patients are often in life-threatening situations, characterized by shortness of breath and signs of pneumonia. Their skin will show signs of inadequate perfusion, accompanied by hypotension. Physical signs, such as swelling of the fingers and toes, priapism, and jaundice, may also guide you in determining whether the patient is experiencing a sickle cell crisis.

If the patient reports pain, ascertain whether the pain is isolated to a single location or whether it is felt throughout the entire body. Has the patient experienced muscle pain or stiffness for unknown reasons? Be alert for signs of acute blood loss (pallor, weak pulse, and hypotension). Look for changes in level of consciousness and symptoms such as vertigo, feelings of fatigue, or syncopal episodes. Ask if the patient has had skin changes such as color changes, burning, or itching. Is the patient having any visual disturbances? Note any bleeding of unknown origin, such as nosebleeds, bloody sputum, and blood in the urine or stool. Is the patient experiencing any gastrointestinal problems, such as nausea, vomiting, or abdominal cramping? Is the patient reporting any chest pain or shortness of breath?

Street Smarts

Many anti-inflammatory drugs (aspirin, ibuprofen) and some herbal supplements (ginkgo, garlic, ginger, ginseng, feverfew) decrease platelet aggregation. Although this effect may be beneficial (such as in myocardial infarction or stroke prevention), these drugs may also increase the tendency to bleed. Always ask patients about medications, including over-the-counter and herbal medications.

In a patient with known sickle cell disease, ask the following questions in addition to obtaining a SAMPLE history:

- Have you had a crisis before?
- When was the last time you had a crisis?
- How did your last crisis resolve?
- Have you had any illness, unusual amount of activity, or stress lately?

Secondary Assessment

The secondary assessment may be performed on scene, en route to the emergency department, or not at all. This will depend on transport time and the patient's condition.

Systematically examine the patient, focusing on major joints at which cells congregate, and obtain your patient's baseline vital signs. Evaluate and document mental status using the AVPU scale.

TABLE 21-5 shows common findings in patients with blood disorders.

Obtain a complete set of vital signs, including a measurement of the patient's oxygen saturation level. In patients experiencing a sickle cell crisis, respirations are normal to rapid, pulse is weak and rapid, and skin is typically pale and clammy with a low blood pressure.

Use pulse oximetry, if available. However, keep in mind that the oxygen saturation reading you obtain may be inaccurate as a result of the patient's anemic state.

Reassessment

It is important to reassess the patient frequently to determine if there have been changes in condition. For example, are there changes in the patient's mental status? Are the ABCs still intact? How is the patient responding to the interventions performed?

Should you adjust or change the interventions? In many patients, you will note marked improvement with appropriate treatment. Document each assessment, your findings, the time of the interventions, and any changes in the patient's condition.

Communication with hospital staff is important for continuity of care. Hospital personnel need to be informed about the patient's history, the present situation, your assessment findings, and your interventions and their results.

Your run report is the only legal document that shows appropriate care was provided. Document your assessment findings clearly as the basis for your treatment. Follow your local protocols for patients who refuse treatment or transport.

Emergency Medical Care of Hematologic Emergencies

Emergency medical care for any patient with problems related to a blood disorder should include the following:

- **Oxygen.** The amount needed and how it is given (that is, bag-mask ventilation, non-rebreathing mask) depend on the severity of the patient's condition and respiratory status. High levels of oxygen are recommended for patients with sickle cell disease to maximize oxygen delivery to the tissues and mitigate the crisis.

TABLE 21-5 Common Findings With Blood Disorders

System	Examples of Common Findings
Level of consciousness	Alterations in level of consciousness, ranging from excitability, agitation, and combativeness, to complete unresponsiveness
Skin	Uncontrolled bleeding, unexplained or chronic bruising, itching, pallor, or jaundice (yellow appearance usually indicates liver problems)
Visual disturbances	Visual disturbances, including blurred vision, decreased vision, tunnel vision, and seeing black or gray spots
Gastrointestinal	Epistaxis (bloody nose), bleeding or infected gums, ulcers, melena (blood in the stool), and liver failure (causes jaundice)
Skeletal	Chronic joint or bone pain or rigidity
Cardiovascular	Dyspnea, tachycardia, chest pain, hemoptysis (coughing up blood)
Genitourinary	Hematuria, menorrhagia, chronic or recurring infections

- **Fluids.** Initiate IV fluid replacement as indicated for the specific disorder or chief complaint. You may need to give IV fluid therapy to counter the patient's dehydration.
- **Transport.** Provide rapid transport to the closest, most appropriate facility.
- **Pharmacology.** Pain management is often necessary, especially in the case of a sickle cell crisis. Follow local protocols.
- **Comfort and rest.** Place the patient in a position of comfort and cover the patient to maintain the body temperature.
- **Psychological support.** Be supportive and communicate with the patient.

Remember that patients may have lived with the disease for a long time and, thus, may have a high pain medication threshold. Consequently, they often require a higher level of analgesia. Nitrous oxide may provide a measure of relief. Follow local protocols for pain management.

Management of Specific Conditions

Distinguishing a true sickle cell crisis from other nonspecific causes of pain can be difficult. In these situations, perform a thorough assessment and contact the hospital to help sort out the signs and symptoms. Medical control should be a resource for you to help problem-solve situations and provide guidance on how to treat your patient. After the patient has arrived at the hospital, care for sickle cell disease might include analgesics for pain, antibiotics to prevent infection, and, depending on the severity of the crisis, a blood transfusion.

In cases of anemia, check and monitor the airway and the patient's breathing closely, administering high-flow oxygen when necessary. The patient's oxygen-carrying capacity is limited, so you want to make sure that the RBCs that are present are being maximized. Check vital signs frequently. Monitor patients closely during fluid replacement; IV fluids do not contain RBCs or blood components, so they may induce unwanted or unexpected bleeding. Do not be surprised if you have to control substantial nosebleeds in any patient with anemia. For patients reporting chest pain, call early for paramedic backup.

Although patients with hemophilia may require IV therapy in cases of unstable hypotension, understand that the patient needs a transfusion or plasma. The patient may also exhibit worsening signs of hypoxia as IV fluid dilutes the blood, further diminishing oxygen levels. Some patients will have substantial pain, so analgesics may be appropriate. Cover patients to maintain body temperature. Although you may be called to treat someone with bleeding of unknown cause only to find that the bleeding stopped before you arrive on scene, you should suggest that the patient receive immediate transport to the hospital or physician follow-up.

It is important to identify DIC and establish treatment early, while not delaying transport to an appropriate facility. Maintain the patient's airway, administer supplemental oxygen, and treat the patient for shock (keep the patient warm, control bleeding, administer IV fluids for hypotension) per local protocol. Patients who have DIC have a poor survival rate; both patients and their family members need strong support. Be optimistic but honest with patients and family, and do not give false hope regarding survival.

YOU are the Provider SUMMARY**1. What are the two types of diabetes, and how do they differ?**

There are two common types of diabetes: type 1 and type 2. Typically, type 1 diabetes develops during childhood. However, type 1 diabetes can, in many cases, develop later in life as well. In type 1 diabetes, no insulin is produced and the patient requires daily injections of supplemental, synthetic insulin to control blood glucose levels.

The most common form of diabetes is type 2 diabetes. In type 2 diabetes, patients produce insufficient amounts of insulin or insulin that does not function effectively. Type 2 diabetes typically develops when the patient is a middle-aged adult, although the disease is becoming more common in younger people. In many people with type 2 diabetes, the pancreas produces enough insulin; however, the body cannot effectively utilize it.

2. What is the function of an insulin pump?

An insulin pump is a small device that consists of an infusion set, a reservoir for insulin, and the pump itself. Such pumps provide improved control of blood glucose levels for many diabetic patients.

3. Should you instruct the patient's wife to turn off the insulin pump?

Yes, instruct the patient's wife to turn off the insulin pump, at least until you are able to obtain the patient's blood glucose level. If the patient is hypoglycemic and the pump is allowed to remain on, and if it is functioning inappropriately, it may decrease the patient's blood glucose level. If the patient is found to be hyperglycemic, then, depending on local protocols, the pump may be turned back on and the patient may be treated for hyperglycemia per protocols.

4. By which route or routes may D₅₀ be administered?

D₅₀ may be administered via the IV or the IO route. Some local protocols may also allow it to be administered rectally, but this is usually a last resort.

5. What are the indications and contraindications for dextrose?

Dextrose should be administered to patients with symptomatic hypoglycemia, altered level of consciousness for unknown reasons, and unresponsiveness with no obtainable patient history, among other reasons. Contraindications for dextrose administration include the presence of increased intracranial pressure or possible intracranial bleeding. Unless the patient is severely hypoglycemic, dextrose should be used with caution in patients suspected of having hypokalemia (low potassium levels), such as patients who are taking diuretics.

6. What is the usual adult dosage of dextrose?

The usual adult dosage of dextrose is 12.5 to 25 g, in 50 to 250 mL of fluid, depending on local protocols. It is therefore important to consult local protocols prior to the administration of any medication.

7. Does this patient require transport to the emergency department?

Yes, this patient requires transport to the emergency department for evaluation. The patient's blood glucose level should not have been low because he has an insulin pump. On the basis of this finding, it is likely that the patient's insulin pump is malfunctioning. If the patient is allowed to refuse transport, he may experience another hypoglycemic episode.

8. Why is it important to reassess the patient's blood glucose level during transport?

It is important to recheck the patient's blood glucose level because of the half-life of dextrose. In the case of a patient with a faulty insulin pump, the insulin may have a longer half-life than that of dextrose, causing rebound hypoglycemia.

YOU are the Provider **SUMMARY** *continued*
EMS Patient Care Report (PCR)

Date: 03-17-21	Incident No.: 201040051	Nature of Call: Unresponsive		Location: 178 Stutzman Street	
Dispatched: 1130	En Route: 1130	At Scene: 1133	Transport: 1208	At Hospital: 1216	In Service: 1226

Patient Information

Age: 41 Sex: M Weight (in kg [lb]): 96 kg (212 lb)	Allergies: None Medications: Insulin Past Medical History: Type 1 DM Chief Complaint: Unresponsive
---	---

Vital Signs

Time: 1134	BP: Not yet obtained	Pulse: Not obtained	Respirations: 12	Spo₂: Not obtained
Time: 1141	BP: 154/88	Pulse: 77	Respirations: 18	Spo₂: 100% on 15 L/min
Time: 1149	BP: 154/78	Pulse: 68	Respirations: 20	Spo₂: 100% on 15 L/min

EMS Treatment (circle all that apply)

Oxygen @ <u>15</u> L/min via (circle one): NC <u>(NRM)</u> Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	<u>Other:</u> 2.5 g D ₅₀

Narrative

EMS dispatched to above location for unresponsive man. On arrival, greeted by patient's wife, who states patient has past medical history of type 1 diabetes, and while she was making lunch, he became confused and then unresponsive. Patient presents responsive to deep painful stimuli, airway patent. Wife asks if she should turn off patient's insulin pump, advised "yes." Initial blood glucose level reads "Lo" (less than 25 mg/dL). Nonrebreathing mask applied at 15 L/min, 18-gauge IV line established to right arm, infusing well with no signs of infiltration. 25 g of D₅₀ administered over 4 minutes, followed by 250-mL bolus of normal saline. Approximately 5 minutes after administration, the patient is AO×4, ABCs intact, refusing all further treatment. Advised the patient of the need to be evaluated at the emergency department because of the possibility of a malfunctioning insulin pump. Patient remains adamant about refusal of services. Contacted Dr. Anderson at Park County Memorial Hospital (PCMH) who spoke to patient. Patient reluctantly agreed to transport. Assisted to ambulance, secured × 3, transport nonemergent to PCMH. En route: vitals, O₂, and IV line as above. Repeat blood glucose level reading of 189 mg/dL. On arrival at PCMH, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- The endocrine system comprises a network of glands that produce and secrete hormones—chemical substances produced by a gland that have special regulatory effects on other organs and tissues.
- The major components of the endocrine system are the hypothalamus, pineal gland, pituitary, thyroid gland, thymus gland, parathyroid gland, adrenal glands, and reproductive organs (gonads). The pancreas is also part of this system; it has a role in hormone production as well as in digestion.
- The main function of the endocrine system is to maintain homeostasis. Maintaining homeostasis requires a response to any change in the body, such as low glucose levels in the blood.
- Thyroid disorders include hyperthyroidism and hypothyroidism. Learn the effects of these on the body so you can distinguish these disorders. Ensure you know how to recognize thyroid storm because it can be life threatening.
- Diabetes is a metabolic disorder in which the body does not sufficiently metabolize glucose. Diabetes can be caused by a lack of insulin or the body's inability to respond to insulin. Insulin is a hormone that enables glucose to enter the cells, where it can be used for energy. Diabetes is typically characterized by polyphagia (increased appetite), polydipsia (substantial thirst), and polyuria (excessive urination), along with deterioration of body tissues.
- There are two types of diabetes. Type 1 diabetes usually starts in childhood and requires daily insulin to control the blood glucose level. Type 2 diabetes usually develops in middle-aged patients and can often be controlled with diet and oral medications. Both are serious systemic diseases that affect the kidneys, eyes, small arteries, and peripheral nerves, especially if the disease is uncontrolled or poorly controlled.
- Prediabetes exists when blood glucose levels or hemoglobin A1c levels are above normal levels, yet not high enough to be diagnosed as diabetes.
- Gestational diabetes is diabetes that a woman develops during pregnancy. It should be managed to stabilize blood glucose levels and minimize potential complications to mother and baby.
- Patients with diabetes have chronic complications that place them at risk for other diseases such as myocardial infarction, stroke, and infections. Most often, however, you will be summoned to treat the acute complications of blood glucose imbalance. These include hyperglycemia (excess blood glucose) and hypoglycemia (low blood glucose).
- Symptoms of hypoglycemia classically include confusion; rapid respirations; rapid pulse; cool, pale skin; diaphoresis; trembling; dizziness; fainting; and a feeling of hunger. This condition, called hypoglycemic crisis, is rapidly reversible with the administration of glucose in oral or IV form, or glucagon intramuscularly. Without treatment, permanent brain damage and death can occur.
- Hyperglycemia is usually associated with dehydration and DKA. It can result in hyperglycemic crisis, marked by rapid (often deep) respirations; warm, dry skin; a weak, rapid pulse; and a fruity breath odor. Hyperglycemia must be treated in the hospital with insulin and IV fluid rehydration.
- Hyperosmolar hyperglycemic nonketotic syndrome (HHNS) is a metabolic derangement that occurs principally in patients with type 2 diabetes who have a secondary illness. It is characterized by hyperglycemia, hyperosmolarity, and an absence of substantial ketosis.
- Because either too much or too little blood glucose can result in an altered mental status, you must perform a thorough history and patient assessment. Check for an emergency

medical identification device (such as a wallet card, necklace, or bracelet), or ask the patient or a family member.

- A patient in hypoglycemic crisis (rapid onset of altered mental status, hypoglycemia) needs sugar immediately. A patient in hyperglycemic crisis (acidosis, dehydration, hyperglycemia) needs insulin and IV fluid therapy. These patients need prompt transport to the hospital for appropriate medical care.
- When you cannot determine the nature of the problem, it is best to treat the patient for hypoglycemia. The risk of increasing the glucose level of a patient who is already hyperglycemic is minimal compared with the benefit of increasing the glucose level of a patient who is hypoglycemic.
- Be prepared to give oral glucose to a responsive patient who is confused or has a slightly decreased level of consciousness and IV or intraosseous dextrose to an unresponsive patient. Do not give oral glucose to patients who are unresponsive or otherwise unable to swallow properly or protect their own airway.
- Dextrose is available in various concentrations: 50% (D₅₀), 25% (D₂₅), and 10% (D₁₀). The total dose of dextrose in these formats is the same; the concentration and volumes differ.
- You may administer glucagon intramuscularly when you cannot obtain IV access and therefore cannot administer dextrose.
- Hematology is the study and treatment of blood-related diseases, such as sickle cell disease or hemophilia.
- Blood is made of two main components: plasma and formed elements (cells). The formed elements include RBCs, WBCs, and platelets, which are transported through the body in plasma.
- RBCs carry oxygen to the tissues. WBCs provide the body with immunity, fight infection, and remove dead cells. Platelets are responsible for clot formation. The bone marrow is the primary site for cell production, and the liver and spleen also have important roles.
- During a blood transfusion, if patients receive a different blood type than their own, a transfusion reaction will occur. Such

a reaction is similar to an anaphylactic reaction; both occur rapidly and can be fatal. Patients receiving blood transfusions must be monitored closely for 30 to 60 minutes.

- Sickle cell disease is an inherited blood disorder that results in the RBCs having an oblong shape instead of a smooth, round shape. This shape inhibits the ability of RBCs to carry oxygen effectively.
- Symptoms of sickle cell disease are typically characterized by pain in the joints, fever, respiratory distress, and abdominal pain.
- Patients with sickle cell disease have chronic complications that place them at risk for other diseases, such as heart attack, stroke, and infection. Most often, however, you will be called on to treat the acute complications of severe pain.
- Anemia is a hemoglobin or RBC level that is lower than normal. Patients with anemia may report feeling worn down, having no energy, or feeling as if they have overexerted themselves. They may also have anginalike pain and be pale.
- Thrombophilia and hemophilia are clotting disorders. Thrombophilia is a tendency to develop blood clots, which can result in thrombosis and obstruct blood flow. Patients with hemophilia are not able to control bleeding because clots do not develop as they should.
- Disseminated intravascular coagulation (DIC) is uncontrolled hemorrhage that results from a life-threatening condition, for example, massive injury and hypotension owing to trauma or possibly sepsis. Remain alert for signs of coagulopathy as you assess and care for critically injured and ill patients.
- Obtain a thorough patient history and SAMPLE history with any patient with a potential blood disorder. The history may reveal that the patient has a known blood disorder, or reveal signs and symptoms that could suggest an undiagnosed blood disorder.
- Do not take a call from a person having a sickle cell crisis lightly. Patients are often in life-threatening situations. They will have signs of inadequate perfusion and of hypotension,

and may have muscle pain, swelling of the fingers and toes, priapism, and jaundice.

- Emergency care for patients with sickle cell disease or a clotting disorder includes

oxygen administration, IV fluid therapy, pain management, comfort measures, psychological support, and transport.

Vital Vocabulary

ABO system The antigen classification given to blood.

acidosis A pathologic condition that results from the accumulation of acids in the body; an increase in extracellular H⁺ ions; a blood pH of less than 7.35.

acute chest syndrome A vaso-occlusive crisis that can be associated with pneumonia; common signs and symptoms include chest pain, fever, and cough.

aerobic metabolism The metabolism that takes place in the presence of oxygen.

anemia A lower-than-normal hemoglobin or red blood cell level.

aplastic crisis A condition in which the body stops producing red blood cells; typically caused by infection.

calcitonin A hormone produced by the parafollicular cells of the thyroid gland that is important in the regulation of calcium levels in the body.

clotting factors Substances in the blood that are necessary for clotting; also called coagulation factors.

coagulopathy Any type of bleeding disorder that interferes with the activation or continuation of the clotting cascade or hemostasis.

cortisol A hormone that stimulates most body cells to increase their energy production.

diabetes mellitus A metabolic disorder in which the ability to metabolize carbohydrates (sugars) is impaired due to a lack of insulin.

diabetic ketoacidosis (DKA) A form of acidosis in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

disseminated intravascular coagulation (DIC) A condition that begins with widespread activation of the clotting cascade, which depletes the

clotting factors and platelets, and eventually results in uncontrolled hemorrhage.

endocrine glands Glands that secrete or release chemicals that are used inside the body.

endocrine system The complex message and control system that integrates many body functions, including the release of hormones.

exocrine gland A gland that excretes chemicals for elimination.

gestational diabetes Diabetes that develops during pregnancy in women who did not have diabetes before pregnancy.

glucagon The hormone released from the alpha cells in the islets of Langerhans that converts glycogen to glucose when the body's blood glucose level drops.

gluconeogenesis A process that stimulates both the liver and the kidneys to produce glucose from noncarbohydrate molecules.

glucose One of the basic sugars; it is the primary fuel, along with oxygen, for cellular metabolism.

glycogenolysis The process by which glycogen is broken down and converted to glucose; facilitated by glucagon.

glycolysis The conversion of glucose into energy via metabolic pathways.

hematologic disorder Any disorder of the blood.

hematology The study and prevention of blood-related disorders.

hematopoietic system The system that includes all blood components and the organs involved in their development and production.

hemolytic crisis A rapid destruction of red blood cells that occurs faster than the body's ability to create new cells.

hemolytic disorders Disorders relating to the breakdown of red blood cells.

hemophilia A congenital abnormality in which the body is unable to produce clots due to a lack of normal clotting factors, resulting in uncontrollable bleeding.

hemostasis Formation of clots to plug openings in injured blood vessels and stop blood flow; the body's natural blood-clotting mechanism.

hemostatic disorders Bleeding and clotting abnormalities.

hormones Substances formed in specialized organs or glands and carried to another organ or group of cells in the same organism; these regulate many body functions, including metabolism, growth, and body temperature.

hyperglycemia Abnormally high glucose level in the blood.

hyperglycemic crisis Unresponsiveness caused by dehydration, a very high blood glucose level, and ketoacidosis.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A metabolic derangement that occurs principally in patients with type 2 diabetes; it is characterized by hyperglycemia, hyperosmolarity, and an absence of significant ketosis.

hypoglycemia Abnormally low glucose level in the blood.

hypoglycemic crisis Unresponsiveness or altered mental status in a patient with diabetes caused by significant hypoglycemia; usually the result of excessive exercise or activity, failure to eat after a routine dose of insulin, or an inadvertent overdose of insulin.

insulin A hormone produced by the islets of Langerhans (an exocrine gland in the pancreas) that enables sugar in the blood to enter the cells of the body; used in synthetic form to treat and control diabetes mellitus.

islets of Langerhans Structures found in the pancreas that are composed of four types of cells; one type, the beta cell, is responsible for the production of insulin.

ketonemia Excess amounts of ketone bodies in the blood.

Kussmaul respirations Deep, rapid breathing; the result of an accumulation of certain acids when insulin is not available in the body.

leukocytosis An elevated white blood cell count, often due to inflammation; other causes include parasitic infections, bone tumors, and leukemia.

leukopenia A reduction in the number of white blood cells.

lipolysis The metabolism (breakdown or destruction) of stored fat that has been released into the circulation.

microangiopathy Microscopic deterioration of vessel walls caused primarily by adherence of blood lipids to vessel walls.

pancreas A flat, solid organ that can also be considered a gland, that lies below the liver and the stomach; it is a major source of digestive enzymes delivered into the duodenum, and produces the hormone insulin; considered both an endocrine gland and an exocrine gland.

plasma A sticky, yellow fluid made mostly of water, but also electrolytes, clotting factors, and glucose, that is a component of blood that carries the blood cells, formed elements, and nutrients and transports cellular waste material to the organs of excretion.

platelets Tiny, disk-shaped elements that are much smaller than the cells; they are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

polydipsia Excessive thirst persisting for long periods despite reasonable fluid intake; often the result of excessive urination.

polyphagia Excessive eating; in diabetes, the inability to use glucose properly can cause a sense of hunger.

polyuria The passage of an unusually large volume of urine in a given period; in diabetes, this can result from wasting of glucose in the urine.

prediabetes A condition identified in people who have certain risk factors associated with type 2 diabetes and exists when blood glucose levels or hemoglobin A1c levels are above normal levels, yet not high enough to be diagnosed as diabetes.

red blood cells (RBCs) The formed elements in the blood that contain hemoglobin and are responsible for carrying oxygen to the tissues; also called erythrocytes.

sickle cell disease A hereditary disease that causes normal, round red blood cells to become oblong, or sickle shaped.

splenic sequestration crisis An acute, painful enlargement of the spleen caused by sickle cell disease.

stem cell A type of cell that can develop into other types of cells in the body; this type of cell retains the ability to divide repeatedly without specializing and allows for continual growth and renewal.

thrombocytopenia A reduction in the number of platelets.

thrombocytosis A condition in which the body produces too many platelets.

thrombophilia A tendency toward the development of blood clots as a result of an abnormality of the system of coagulation.

thrombosis A blood clot, either in the arterial or venous system.

thyroid-stimulating hormone Hormone that stimulates the release of thyroid hormone from the thyroid gland.

thyroid storm A rare, life-threatening condition that may occur in patients with thyrotoxicosis. The condition is usually triggered by a stressful event or increased volume of thyroid hormones in the circulation.

type 1 diabetes The type of diabetic disease that usually starts in childhood and requires insulin for proper treatment and control.

type 2 diabetes The type of diabetic disease that usually starts later in life and often can be controlled through diet and oral medications.

vaso-occlusive crisis Ischemia and pain caused by sickle-shaped red blood cells that obstruct blood flow to a portion of the body.

white blood cells (WBCs) Blood cells that have a role in the body's immune defense mechanisms; they provide immunity, fight infection, and remove dead cells; also called leukocytes.

Chapter 22

Immunologic Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Immunology

Recognition and management of shock and difficulty breathing related to

- Anaphylactic reactions (pp 1122, 1123)

Anatomy, physiology, pathophysiology, assessment, and management of hypersensitivity disorders and/or emergencies

- Allergic and anaphylactic reactions (pp 1112–1128)

KNOWLEDGE OBJECTIVES

1. Understand and define the terms *allergic reaction* and *anaphylaxis*. (p 1112)
2. Describe the purpose of the immune system. (p 1112)
3. Discuss the process that begins when a foreign substance is detected in the body (primary response). (p 1114)
4. Explain the roles of basophils and mast cells in the immune response process. (p 1114)
5. Describe the process that occurs when the body undergoes a secondary response. (pp 1114–1115)
6. Explain the difference between a local response and a systemic response to allergens. (pp 1116–1117)
7. Explain the roles of two types of chemical mediators, histamine and leukotrienes, in the immune response process. (pp 1117–1118)
8. List and compare the signs and symptoms of an allergic reaction with those of anaphylaxis. (p 1120)
9. Describe the assessment process for a patient with an allergic reaction. (pp 1121–1124)
10. Explain the importance of managing the airway, breathing, and circulation of a patient who is having an allergic reaction. (p 1125)
11. Review the process for providing emergency medical care to a patient who is experiencing an allergic reaction. (pp 1124–1128)
12. Explain the rationale, including communication and documentation considerations, when determining whether to administer epinephrine to a patient who is having an allergic reaction. (pp 1123–1124)
13. List the types of insect stings that may cause an allergic reaction, and describe specific treatment of patients with such stings. (pp 1129–1130)
14. Discuss patient education related to prevention and management of anaphylaxis and allergic reactions. (pp 1128–1131)

SKILLS OBJECTIVES

1. Demonstrate how to use an EpiPen auto-injector. (p 1127, Skill Drill 22-1)
2. Demonstrate how to remove a stinger from a bee sting and proper patient management following its removal. (pp 1129–1131)

Introduction

Every year, more than 50 million Americans experience an allergic reaction, and allergies are the sixth-leading cause of chronic illness in the United States.¹ When managing allergy-related emergencies, you must be aware of the possibility of acute airway obstruction and cardiovascular collapse and be prepared to treat these life-threatening complications. You must also be able to distinguish between the body's usual response to an allergen and an **allergic reaction**—an exaggerated immune response to any substance—that may require **epinephrine**, or **anaphylaxis**—an extreme systemic form of an allergic reaction involving two or more body systems. Your ability to recognize and manage the many signs and symptoms of allergic reactions may be the only thing standing between a patient's life and imminent death.

This chapter begins by describing the physiology of the body's immune response and the pathophysiology of an allergic reaction—that is, how an immune response can evolve into a potentially life-threatening event. It discusses the general assessment of patients who may be having an allergic reaction and how to care for them, including the administration of epinephrine. Finally, the chapter describes specific stings and bites from bees, wasps, yellow jackets, hornets, and fire ants.

Anatomy and Physiology Review

Anatomy Review

The **immune system** protects the human body from substances and organisms that are foreign to the body. Without the immune system for protection, life as you know it would not exist. You would be under constant attack from any type of invader, such as a bacterium or virus, that wanted to make your body a home. Fortunately, most people have immune systems that are well equipped to detect unauthorized visits or invading attacks by foreign substances.

The body protects itself via two types of systems: cellular immunity and humoral (ie, related to the body's fluids) immunity. In **cellular immunity**, also called *cell-mediated* immunity, the body produces specialized white blood cells called *T cells* that attack and destroy invaders. In **humoral immunity**, B cell lymphocytes produce antibodies that dissolve in the plasma and lymph to wage war on invading organisms. The cells producing immunity factors are located throughout the body in the lymph nodes, spleen, and gastrointestinal tract. Their goal is to intercept foreign invaders as they enter the body, thereby limiting the spread and damage of these organisms.

YOU are the Provider

Part 1

You are dispatched to the home of a 46-year-old man with a possible allergic reaction. On arrival, you are greeted by the patient's wife. She directs you to the patient, who is seated on the sofa. The patient states that he just started a new antibiotic for an upper respiratory infection, and now he itches all over and a large rash is developing on his torso.

1. What is the major difference between an allergic reaction and anaphylaxis?
2. How are the treatments for these two conditions the same? How do they differ?

Given the right person and the right circumstances, almost anything can be an **allergen**, a substance that triggers the body's immune system and causes an allergic reaction. For example, animal bites, food, latex gloves, and even semen can all be allergens, the antigens or substances that produce allergic symptoms in a patient. The most common allergens, however, fall into one of the following five general categories:

- **Insect bites and stings.** When an insect bites or stings you, the act of injecting its venom is called **envenomation**. Envenomation by a honeybee, wasp, ant, yellow jacket, or hornet may cause a localized reaction, causing swelling and itching at the site, or a severe and systemic reaction (ie, anaphylaxis).
- **Medications.** If the medication is injected, the reaction may be immediate (within 30 minutes) and severe. Reactions to oral medications may take more than 30 minutes to appear but can also be very severe. The fact that a person has taken a medication once without experiencing an allergic reaction is no guarantee that the person will not have an allergic reaction to the same medication with subsequent exposure.
- **Plants.** People who inhale dust, pollen, mold, mildew, or other organic materials to which they are sensitive may experience an allergic

reaction. Some common plant allergens include ragweed, ryegrass, maple, and oak.

- **Foods.** Eating certain foods such as shellfish and peanuts may result in a relatively slow (more than 30 minutes) reaction; however, the reaction still can be quite severe. It is possible for a patient to be unaware of the exposure; for example, a person allergic to peanuts may eat something without knowing that one of the ingredients is peanuts.
- **Chemicals.** Certain chemicals, makeup, soap, hair dye, latex, and various other substances can cause severe allergic reactions. Latex is of particular concern to health care providers. For some, simply being in the same room as someone wearing powdered latex gloves can cause a reaction. It is a good practice to routinely use latex alternatives such as nitrile gloves. Follow your local protocol.

Most allergens are usually harmless substances that do not pose a threat to other people—for example, milk, eggs, chocolate, and strawberries. An **antibody** is a protein the body produces in response to an **antigen** (the foreign invader). This protein (globulin) is found in the plasma—a characteristic that inspired its other name, *immunoglobulin* (Ig). **TABLE 22-1** lists the common antibodies, their actions, and locations.

TABLE 22-1 Antibodies		
Antibody	Action	Location
IgA	Provides localized protection to mucous membranes. Stress can lower the IgA level, making the body more susceptible to infection.	Tears, saliva, mucus, breast milk, gastrointestinal secretions, blood, and lymph
IgD	Thought to stimulate antibody-producing cells to make antibodies.	Blood, lymph, and the surface of B cells
IgE ^a	Responds in allergic reactions.	Located on mast cells and basophils
IgG	Provides protection against bacteria and viruses; enhances phagocytosis; neutralizes toxins; triggers the complement system.	Blood, lymph, and intestines
IgM	One of the first antibodies to appear; causes agglutination and lysis of microbes. ABO agglutinins are IgM antibodies.	Blood, lymph, and the surface of B cells

Abbreviation: Ig, immunoglobulin

^aThe IgE antibody is the primary antibody of concern during allergic and anaphylactic reactions.

Foreign substances can invade the body through the skin, the respiratory tract, or the gastrointestinal tract (**TABLE 22-2**). Invasion through the skin may come in the form of injection or absorption. In **injection**, the invading substance pierces the skin and deposits foreign material into the skin. Bees and hornets are often the cause of this type of invasion. **Absorption** occurs when foreign material is deposited on the skin and slowly absorbed through the skin. Invasion by allergens does not stop at the skin; they may also enter the respiratory tract as the patient quietly breathes. Following this kind of **inhalation** exposure, the foreign substance may advance through the respiratory system and launch its attack from the lungs. Pet hair and dander, peanuts, and many plants may enter the body through this type of exposure. The final way allergens attack the body is through the gastrointestinal tract via **ingestion**. Many different foods, such as strawberry shortcake, a mushroom and cheese omelet, or peanut butter pie, can cause an allergic reaction; medications also can cause a reaction through this route. Allergens that are injected or inhaled tend to cause the most severe reaction.

Physiology Review

When a foreign substance invades the body, the body goes on alert and initiates a series of responses. The first encounter with the foreign substance begins the **primary response** and mainly involves the white blood cells—the cells that fight infection in the body. Cells (macrophages) immediately greet, confront, and engulf the invaders to determine whether they are allowed in the body. If the body is unable to identify the invader, it uses immune cells to record the salient features of this substance. These cells record one or two of the proteins on the surface of the invading substance and then design antibodies to match each substance. These antibodies are intended to match up with the antigen and inactivate it.

Through the primary response, the body develops **sensitivity**—that is, the ability to recognize the foreigner the next time it is encountered. To determine whether the substance is “one of us,” the body records enough details to assist in future identification of the substance and production of antibodies that match up perfectly with the invading antigen. The body then sends out these details to the rest of the body by placing the specific antibodies on two types of cells: **basophils** and **mast cells**. Basophils are stationed in specific sites within the tissues. Mast cells are on patrol through the connective tissues, bronchi, gastrointestinal mucosa, and other vulnerable border areas that act as barriers to foreign invaders.

The basophils and mast cells produce the body’s “chemical weapons,” known as **chemical mediators**. These cells contain granules filled with a host of powerful substances that are ready to be released to fight invading forces of antigens. As long as the body is not invaded by one of the previously identified foreign substances, the granules are kept encapsulated in their protective walls and remain inactive. However, if an antigen invades the body and combines with one of the antibodies, the granules are ejected from the mast cells and detonated. Degranulation is the process in which granules burst, releasing their powerful contents. The chemical mediators are then released into the surrounding tissue and the bloodstream.

The chemical mediators—histamine and leukotrienes—launch and maintain the immune response. They summon more white blood cells to the area to battle the invading force. They also increase blood flow to the area under attack by dilating the blood vessels and increasing capillary permeability. These actions are useful when a small invasion occurs to a limited area but can be extremely dangerous when they spread throughout the body. Chemical mediators cause the local effects of an allergic reaction seen in the body. When they have systemic effects, the chemical mediators cause the signs and symptoms of anaphylactic reactions (**FIGURE 22-1**).

As a health care provider, you exploit the body’s ability to protect itself. For example, vaccines are administered to produce **immunity** against a disease. A vaccine contains a killed or weakened version of a disease-causing organism or one of its proteins. The body develops

FIGURE 22-1 The sequence of events in anaphylaxis. **A.** The antigen is introduced into the body. **B.** The antigen-antibody reaction occurs at the surface of a mast cell. **C.** The mast cell chemical mediators release. **D.** The specific antibody reacts with its corresponding antigen. **E.** Chemical mediators exert their effects on end organs.

© Jones & Bartlett Learning.

antibodies in response to the vaccine that enable it to produce an immune response that neutralizes an invading disease (caused by a more potent form of the pathogen found in the vaccine) before it can establish itself and damage the body. Thus, the body develops antibodies in a controlled way through vaccination. When the hepatitis B vaccine is administered, for example, a small amount of the inactivated parts of the hepatitis B virus (HBV) enters the body. The body identifies this virus and produces antibodies to it; these antibodies then become distributed throughout the body. If an immunized person is later exposed to HBV, the virus may invade the body. Once in the body, the virus begins to set up residency and reproduce. At this point, the wandering immune cells identify the HBV as something that does not belong in that area of the body. The alarm sounds, and the body begins aggressive production of the antibodies

to counter hepatitis, sending these cells to kill the HBV and clean up residual traces of the invasion. This intense response to the invading virus is called the **secondary response**. Meanwhile, the “contaminated,” immunized person remains unaware of the battle raging inside their body.

This battle is termed **acquired immunity**. In this type of immunity, the administration of a vaccine allows the body to produce antibodies without having to experience the disease. Vaccinations against measles, mumps, and poliomyelitis are examples of acquired immunity. By contrast, in **natural immunity**, the body encounters the antigen and experiences a full immune response but with all the effects of the disease. Having the measles, for example, causes the body to produce antibodies to this pathogen, but the drawback is that the person has the itching, rash, and high fever associated with the disease.

Words of Wisdom

Use of the poliomyelitis vaccine has resulted in herd immunity, which occurs when a group of people are immunized against a substance. This immunization protects the entire group by decreasing the number of people who are able to contract the disease, thereby protecting all members of the group. Other vaccines that have led to herd immunity include the measles, mumps, and rubella (MMR) vaccine as well as the pertussis vaccine. Herd immunity can be lost when pediatric immunization rates decline, leaving more members of the group vulnerable to developing a disease.

Pathophysiology

An alert and responsive immune system is essential to life and health. Unfortunately, sometimes the immune system becomes overzealous in defending the body. The resulting conditions may range in severity from hay fever to anaphylaxis, and exist along the spectrum from a simple annoyance to a life-threatening crisis. During these abnormal reactions, the immune system becomes hypersensitive to one or more substances. The body often has these reactions to substances that should not be identified as harmful by the immune system—substances such as ragweed, strawberries, and penicillin (**FIGURE 22-2**).

Contrary to what many people might think, an allergic reaction is not caused directly by an outside

FIGURE 22-2 A severe allergic reaction to medication.

Courtesy of Carol B. Guerrero.

stimulus, such as a bite or sting. Rather, it is a reaction by the body's immune system that occurs when a person has been previously exposed or sensitized to a substance or allergen.

Allergic Reactions Versus Anaphylaxis

An allergic reaction may be mild and localized, or it may be systemic. In a **local reaction**, the body limits its response to a specific area after being exposed to a foreign substance; the swelling around an insect bite is an example. By comparison, a **systemic reaction** occurs throughout the body, possibly affecting multiple body systems. This kind of reaction is seen when a person who is allergic to strawberries, for example, has swelling and hives all over

YOU are the Provider

Part 2

As you expose the patient's chest, you observe the following:

Recording Time: 1 Minute

Appearance	Anxious, flushed
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent; mild audible wheezes; no stridor
Breathing	Rapid at 36 breaths/min
Circulation	Absent distal pulses; skin is mottled

- What is the significance of stridor not being present during airway assessment?

the body after eating strawberries or a food containing strawberries. The patient may also experience **hypersensitivity**, which occurs when a person reacts with exaggerated or inappropriate allergic symptoms after coming in contact with a substance perceived by the body to be harmful.

Although most anaphylactic reactions are not fatal, the number of patients who die from anaphylaxis may be greatly underreported because not all anaphylactic deaths are recognized as such. Anaphylactic events may be mistaken for heart attacks, heatstroke, or many other conditions.² In cases of anaphylaxis with known causes, medications produce the most allergy-related deaths.¹

Words of Wisdom

The term *anaphylaxis* was first used in 1902, when Portier and Richet were vaccinating dogs with sea anemone toxin. After the second dose of the toxin, one of the dogs died. Because this response was against a substance intended to provide protection, it was referred to as *anaphylaxis* (meaning without protection). The term is not entirely accurate, however; the fundamental problem in an anaphylactic reaction is not a lack of protection but rather overprotection. That is, anaphylaxis is a form of allergy—an extreme and devastating form—and an allergy represents the body's protective immune system gone overboard.

To anticipate anaphylaxis, of course, it would be useful to be able to identify people who are at greatest risk for this type of reaction. Neither race nor gender seems to affect the incidence of anaphylaxis. Diseases related to allergies, such as allergic rhinitis, asthma, and atopic dermatitis, increase the potential for anaphylactic reactions.

The other major factors associated with anaphylaxis are the route of exposure to the allergen and the time between exposures. Although a severe reaction can occur by any route, the longer the time between exposures to a substance, the less likely it is that a severe anaphylactic reaction will occur. This pattern is thought to reflect the decreased production of the specific Ig or antibody cells in the body over time.

Anaphylaxis is classified as a response mediated by IgE antibodies, whereas an **anaphylactoid reaction** is a response that does not involve IgE

antibody mediation. The exact mechanism is unknown, but an anaphylactoid event may occur without the patient being previously exposed to the offending agent. Examples of triggers of anaphylactic reactions include nuts, fish, and latex. Anaphylactoid triggers, by comparison, include some contrast materials given before radiography, morphine-derived medications, and aspirin. Although the process that causes the reaction is different, the patient presentation is the same and the reactions should be treated in the same manner because both can be life threatening.

Words of Wisdom

Anaphylaxis and anaphylactoid responses are indistinguishable in the field. Treat all patients based on individual presentation.

Pathophysiologic Response

The immune cells of the person with allergies are more sensitive than the immune cells of a person without allergies. Although these cells have the capability to recognize and react to dangerous invaders such as bacteria and viruses, they also identify harmless substances as potential threats.

When the invading substance enters the body, the mast cells recognize it as potentially harmful and begin releasing chemical mediators. The two types of chemical mediators are histamine and leukotrienes. **Histamine** causes the blood vessels in the local area to dilate and the capillaries to leak. **Leukotrienes**, which are even more powerful, are released and cause additional dilation and leaking. White blood cells are called to the area to help engulf and destroy the enemy, and platelets begin to collect (aggregate) and clump together. In most cases, this overreaction to harmless invaders is usually restricted to the local area being invaded. The runny, itchy nose and swollen eyes associated with hay fever are examples of a local allergic reaction.

In the case of anaphylaxis, the person is not so lucky. Chemical mediators are released, and the effect involves more than one system throughout the body (**TABLE 22-3**). An initial effect may be seen from the release of histamine, with secondary effects following a few hours later when the remainder of the chemicals are released.

TABLE 22-3 Physiologic Effects of Chemical Mediators

Mediator	Physiologic Effects
Histamine	• Systemic vasodilation • Increased permeability of blood vessels • Decreased cardiac contractility • Decreased coronary blood flow • Dysrhythmias • Bronchoconstriction • Pulmonary vasoconstriction
Leukotrienes (slow-reacting substances of anaphylaxis)	• Vascular permeability • Bronchoconstriction • Decreased force of cardiac contraction • Decreased coronary blood flow • Dysrhythmias • More potent than histamine (thousands of times) • React more slowly than histamine
Platelet-activating factor	• Platelet aggregation • Causes histamine release
Serotonin	• Pulmonary vasoconstriction • Bronchoconstriction

© Jones & Bartlett Learning.

The release of histamine causes immediate vasodilation, which often presents as flushed (erythematous) skin and sometimes leads to hypotension. It also increases vascular permeability, which results in **angioedema** (swelling of the face and tongue), fluid secretion, and fluid loss. Edema can present as **urticaria** (hives) (**FIGURE 22-3**), airway constriction, and increased fluids in the airway. Histamine similarly causes smooth muscle contraction, especially in the respiratory and gastrointestinal systems. This results in laryngospasm or bronchospasm and abdominal cramping. Finally, histamine decreases the contractility (inotropic effects) of the heart. When this effect is coupled with vasodilation, the person may experience profound hypotension. Dysrhythmias resulting from hypoperfusion and hypoxia are also common.

Later responses from the much more powerful leukotrienes compound the effects of histamine. The person's respiratory status will become even more compromised as these highly

**FIGURE 22-3** Urticaria, or hives, may appear following exposure to an allergen and is characterized by multiple, small, raised areas on the skin. Urticaria may be one of the warning signs of an impending anaphylactic reaction.

© Charles Stewart MD, EMDM, MPH.

potent bronchoconstrictors are released. In addition, the release of leukotrienes causes coronary vasoconstriction, which contributes to a worsening cardiac condition and myocardial irritability. Leukotrienes are also associated with increased vascular permeability, further contributing to the state of hypoperfusion.

The remaining chemical mediators continue to worsen the situation as they undertake what they determine as steps to protect the body from this foreign invader. As a result of these activities, when the body undergoes an anaphylactic reaction, the person may not survive without immediate intervention.

Words of Wisdom

- Inotropic effect: affecting the strength of the contraction of cardiac muscle
- Chronotropic effect: affecting the heart's rate of contraction
- Dromotropic effect: affecting the conduction speed in the atrioventricular node and, consequently, the rate of electrical impulses through the heart

Clinical Symptoms of Anaphylaxis

The skin is the body's first line of defense against would-be invaders, so skin symptoms are often the first indications of anaphylaxis. Initially, the person may be aware of feeling warm and flushed. **Pruritus** (itching) is another early sign, which is a result of vasodilation and capillary leaking. The area around the

eyes is often susceptible to this effect, which causes swollen, red eyes. Angioedema may contribute to airway compromise. You may also note swelling of the hands and feet. Histamine is responsible for the urticaria experienced by a patient with anaphylaxis.

The most common complaints are usually respiratory symptoms, which often present as dyspnea (shortness of breath) and tightness in the throat and chest. You may also note **stridor** and/or hoarseness. These signs and symptoms are often a result of upper airway swelling in the laryngeal and epiglottic areas. Affected patients may complain of a lump in the throat. The lower airway is often involved as well. Bronchoconstriction and increased airway secretions may result in wheezes and crackles. It is not uncommon for the patient to cough or sneeze as the body tries to clear the airway. These symptoms may progress slowly or alarmingly fast. You may have only 1 to 3 minutes to halt this rapid, life-threatening process.

Cardiovascular symptoms are serious complications of anaphylaxis. Histamine and leukotrienes work directly on the heart to decrease its contractility. The resulting decrease in cardiac output is complicated by vasodilation (in which the blood vessels widen) and increased capillary permeability,

leading to blood pooling at the capillary beds, further decreasing the amount of fluid returned to the heart, despite constriction of the coronary arteries. As cardiac output declines, perfusion decreases, resulting in ischemia and the potential for cardiac dysrhythmias. As the fluid leaks out of the capillaries, the intravascular system is left short on fluid. (Up to 50% of the vascular volume can be shifted to the extravascular space within 10 minutes of exposure to an antigen.) Instead of responding normally to the fluid loss and constricting, the blood vessels do just the opposite: they dilate. The already low vascular volume becomes totally inadequate, and hypotension reigns. In response to the low blood pressure, the heart rate increases, putting stress on an already compromised heart. In this situation, tachycardia, flushed skin, and hypotension are synonymous with anaphylactic shock.

Remember that the body will not tolerate an acute blood loss of greater than 20% of blood volume. When substantial volume moves from the intravascular space to the extravascular space, it has the same effect as external blood loss. The patient will exhibit signs of shock, including substantial changes in vital signs: increased heart rate, increased respiratory rate, and decreased blood

YOU are the Provider

Part 3

The local fire unit arrives on scene and assists your partner in bringing in the stretcher while you continue your assessment. The patient states that he visited his primary physician this morning; the physician prescribed the penicillin for an upper respiratory infection. The patient got the prescription filled after his visit and took the initial dose approximately 1 hour ago, with lunch. Approximately 30 minutes ago, an itching sensation developed, along with the rash. While the patient is talking, you notice an increase in his work of breathing. You place the patient on 100% oxygen via nonrebreathing mask and begin taking vital signs.

Recording Time: 5 Minutes

Respirations	40 breaths/min; wheezes bilaterally
Pulse	Absent radial pulses; carotid, 138 beats/min
Skin	Discolored, swollen patches on torso, extending to arms and legs
Blood pressure	76/32 mm Hg
Oxygen saturation (SpO₂)	93% on 100% oxygen
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

4. In which position should this patient be placed?
5. Based on his presentation, what is the definitive treatment for this patient?

pressure. Hypotension is seen sooner in patients with anaphylactic shock, as opposed to hypovolemic shock, owing to vasodilation caused by the release of histamine, preventing the body from compensating.

Gastrointestinal symptoms also may be part of an anaphylactic response, particularly if the offending antigen has been ingested. Abdominal cramping is a common presentation, but nausea; bloating; vomiting; abdominal distention; and profuse, watery diarrhea also may be present.

Patients may present with central nervous system symptoms in response to decreased cerebral perfusion and hypoxia. These symptoms include headache, dizziness, confusion, and anxiety. A sense of impending doom aptly represents the patient's sense of being near death. A patient who expresses a sense of impending doom requires rapid assessment and treatment.

TABLE 22-4 summarizes the signs and symptoms of anaphylaxis compared with those of an allergic reaction. Anaphylaxis may present as

TABLE 22-4 Common Signs and Symptoms of Allergic Reactions and Anaphylaxis

	Allergic Reaction	Anaphylaxis ^a
Respiratory system	• Sneezing or an itchy, runny nose (initially) • Tightness in the chest or throat • Irritating, persistent, dry cough • Hoarseness • Rapid, labored, or noisy respirations • Wheezing, stridor, or both	• Sneezing • Tightness in the chest or throat • Coughing • Stridor • Hoarseness • Lump in throat • Dyspnea • Wheezes • Crackles
Circulatory/ cardiovascular system	• Increase in pulse rate (initially) • Decrease in blood pressure • Pale skin and dizziness	• Tachycardia • Hypotension (can be profound) • Dysrhythmias
Skin	• Flushing, itching, or burning skin • Hives (urticaria) • Swelling, especially of the face, neck, hands, feet, and tongue • Swelling and cyanosis or pallor around the lips • Warm, tingling feeling in the face, mouth, chest, feet, and hands	• Warm, flushed skin • Itching (pruritus) • Hives (urticaria) • Swollen, red eyes • Swelling of the face, neck, hands, feet, and tongue
Gastrointestinal system	• Abdominal cramping	• Abdominal cramping • Nausea • Bloating • Vomiting • Abdominal distention • Profuse, watery diarrhea
Neurologic system	• Anxiety; a sense of impending doom • Headache • Decreasing mental status	• Anxiety and restlessness • Sense of impending doom • Headache • Altered mental status • Dizziness • Confusion • Loss of consciousness and coma
Other findings	• Itchy, watery eyes	• Not applicable

^aSigns and symptoms of anaphylaxis include the signs and symptoms of allergic reactions, plus additional signs and symptoms. Anaphylaxis is a systemic reaction, whereas allergic reactions are usually mild and localized.

affecting any two or more of these body systems, so the picture can be confusing at times. Think of a patient with anaphylaxis as experiencing three types of shock: (1) cardiogenic shock due to decreased cardiac output, (2) hypovolemic shock due to fluids leaking into the tissues, and (3) neurogenic shock due to inability of the blood vessels to constrict.

Patient Assessment

Assessment of a patient who is experiencing an anaphylactic reaction can be highly challenging. You may have to simultaneously assess the patient, identify the problem, and intervene within seconds of arriving on the scene to save the patient's life. Suspicion for anaphylaxis must be high if any of the pertinent symptoms are present. You may not have a second opportunity because the patient's condition may deteriorate before your eyes.

The response to antigens may occur in a multistep manner, with the immediate acute response being followed later by a delayed response. Alternatively, the reaction can be either acute or delayed. Acute reactions have a rapid onset and typically result in the most life-threatening situations. Delayed reactions may take hours or longer to manifest, and the response is not usually as exaggerated. A *prolonged, persistent reaction* is one in which anaphylaxis symptoms continue over time from 5 to 72 hours.³ In a *biphasic response*, the patient experiences an initial reaction, appears to recover, and then experiences a recurrence of symptoms. To help minimize the effects of a delayed reaction that occurs alone or as part of a biphasic response, all patients who experience an allergic reaction should be encouraged to seek medical attention.

Scene Size-up

First and foremost, ensure the scene is safe. The patient's environment or recent activity may indicate the source of the reaction, such as an insect sting or bite, a food allergy triggered by eating at a restaurant, or a new medication regimen. A respiratory problem reported by dispatch may be an allergic reaction. However, if many people are affected, the scene could involve an inhaled poison or a terrorist event. Never enter a scene where more than one person is experiencing the same symptoms with a similar onset. Consider the need for additional or

specialized resources, and call for those resources immediately.

Consider that traumatic injury may also be present, secondary to the medical emergency. Determine the mechanism of injury or nature of illness. Look for bee stingers or contact with chemicals and other indications of a reaction.

Primary Survey

Perform the primary survey of the patient. The patient's presentation will give you an indication of the severity of the problem. Any change in mental status in an anaphylactic patient should direct you to immediately begin airway evaluation and management.

Quickly assess the patient for respiratory symptoms, such as dyspnea, tightness in the throat and chest, increased work of breathing, use of accessory muscles, head bobbing, tripod positioning, nostril flaring, prolonged expiration, and abnormal breath sounds. A noisy upper airway is a concern in any patient, but even more so in an anaphylactic patient because it may be an early sign of impending airway occlusion. Assess breath sounds for **wheezing**. Exhalation, normally the passive, relaxed part of breathing, becomes harder as the patient tries to cough up the secretions or move air past the constricted airways. As the patient's condition worsens and the lungs become tighter (closed) and less ventilated (hypoventilation), breath sounds may even diminish to the point of being almost silent. Stridor, a harsh, high-pitched sound heard on inspiration, occurs when swelling in the upper airway (near the vocal cords and throat) begins to close off the airway. It can eventually lead to total obstruction.

Position an alert patient in a tripod position, leaning forward; this position will facilitate air entry into the lungs and may help the patient to relax. Do not hesitate to initiate high-flow oxygen therapy. For unresponsive patients or those with an altered mental status who are in severe respiratory distress, you may have to assist ventilations using a bag-mask device, attached to a high concentration of oxygen. The positive-pressure ventilations you provide will force air through the swelling in the airway and into the lungs while you await more definitive treatment. Standard airway procedures and positive-pressure ventilation are described in detail in Chapter 11, *Airway Management*.

Although respiratory complaints are most common, some patients in anaphylaxis may present primarily with signs and symptoms of circulatory distress, such as hypotension. Palpate for the presence and quality of a radial pulse to quickly identify how the patient's circulatory system is responding to the reaction. If the patient is unresponsive and pulseless, begin basic life support measures and use an automated external defibrillator if necessary. Assess for a rapid pulse rate; pale, cool, cyanotic or red, moist skin; and delayed capillary refill, all of which may indicate hypoperfusion. Treatment for shock includes administering oxygen, placing the patient supine, and preventing the loss of body heat. The definitive treatment for shock resulting from anaphylaxis is epinephrine, discussed later in this chapter. For more information on how to treat shock, see Chapter 14, *Shock*.

Expose and evaluate the skin for erythema, rashes, edema, moisture, pruritus, and urticaria. Pallor and cyanosis may be present as well. Bite or sting marks may be observed, depending on the cause of the allergic reaction.

If anaphylaxis is suspected, or if a relatively mild allergic reaction appears to be worsening, immediately transport to the closest, most appropriate facility. Be sure to take along the patient's medications (eg, auto-injectors and inhalers). Make your transport decision based on findings in the primary survey. Anaphylaxis may present as affecting two or more body systems, so the picture can be confusing at times. Use your assessment skills to identify the potential for anaphylaxis, take aggressive action to treat the patient, and stop the anaphylactic process as rapidly as possible. If the patient has signs of respiratory distress or shock, treat those conditions and transport. In contrast, if the patient is calm and does not exhibit severe signs and symptoms, continue the assessment at the scene.

Words of Wisdom

Think of a patient with anaphylaxis as simultaneously experiencing three types of shock:

- Cardiogenic shock due to decreased cardiac output
- Hypovolemic shock due to fluids leaking into the tissues
- Neurogenic shock due to inability of the blood vessels to constrict

History Taking

Investigate the patient's chief complaint or history of the present illness. Identify associated signs and symptoms such as wheezing or a rash, and pertinent negatives such as lack of nausea or vomiting or no chest pain.

If the patient is responsive, begin by obtaining the SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history (including OPQRST-I [Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions]) and the following information specific to allergic reactions:

- **Have any interventions already been completed?** Prior to your arrival, the patient or other emergency medical responders may have begun treatment with medication, such as an epinephrine auto-injector, antihistamines such as chlorpheniramine (Chlor-Trimeton) or diphenhydramine (Benadryl), or an inhaler that contains a bronchodilator (such as albuterol or metaproterenol) or aerosolized epinephrine (such as Primatene Mist or racemic epinephrine). If the patient has an EpiPen or used one, be aware that some EpiPens come with two doses. Do not discard the second dose.
- **Has the patient experienced a severe allergic reaction in the past?** If so, what happened? The patient's answers may indicate how severe the present reaction may become.
- **Be alert for any statements regarding previous exposure to common antigens.** For example, if the patient just ate peanuts, asking about previous ingestions may be useful. A severe reaction may occur at the second exposure to an antigen, so the patient might not know about the allergy. Asking about medications, and in particular new medications, may also help identify the antigen.

Street Smarts

If the patient used an epinephrine auto-injector prior to EMS arrival and does not show improvement, check the expiration date of the medication. Patients may not refill prescriptions because of the high cost.

Secondary Assessment

Next, perform a physical examination. If the patient is exhibiting life-threatening signs and symptoms, perform the examination en route to the hospital.

If you have not already done so, auscultate for abnormal breath sounds such as wheezing or stridor, and carefully inspect the skin for swelling, rashes, hives, and signs of the source of the reaction—for example, bite, sting, or contact marks. A rapidly spreading rash can be concerning because it may indicate a systemic reaction. The skin may appear pale or cyanotic and cool; however, red, hot skin is typical in the early stages, suggesting a systemic reaction as the blood vessels lose their ability to constrict and blood moves outward and closer to the skin. If a systemic reaction continues, the body will have difficulty supplying blood and oxygen to the vital organs. One of the first signs that this has occurred will be altered mental status, as the brain is deprived of oxygen and glucose.

Vital signs help determine whether the body is compensating for the stress imposed on the body by the reaction. Assess baseline vital signs, including the pulse and respiratory rate, blood pressure, pupillary response, and oxygen saturation. Rapid respiratory and pulse rates may indicate respiratory distress or systemic shock. Tachycardia and hypotension are ominous signs, indicating systemic vascular collapse and shock. Remember that skin signs may be unreliable indicators of hypoperfusion, as they may vary widely or be hidden by rashes, swelling or dark pigmentation.

You should use a cardiac monitor in your assessment because dysrhythmias may be associated with anaphylaxis. Monitoring through pulse oximetry may alert you to low oxygen saturation, which will assist in identifying the patient's degree of respiratory distress. However, it is important to remember that factors such as decreased circulation and exposure to carbon monoxide can render pulse oximetry readings unreadable. End-tidal carbon dioxide (ETCO₂) levels may be elevated in anaphylaxis and are more reliable than pulse oximetry in low-perfusion states. In nonintubated patients, the waveform is more important than the numeric value obtained during capnography because capnography results are not always reliable in such patients. The partial pressure of carbon dioxide will be elevated, and the ETCO₂ value will be normal to low because of poor

alveolar gas exchange. The decision to administer oxygen to a patient experiencing an allergic reaction should be based on careful assessment of the patient's airway patency, work of breathing, and abnormal breath sounds on auscultation, not solely on the pulse oximetry readings. The bottom line is that you should never withhold supplemental oxygen from a patient experiencing difficulty breathing, regardless of pulse oximetry values.

Assessment Pearls

Rapidly assess for the following when the patient is possibly experiencing an allergic reaction:

- Agitation, altered mental status
- Slurred speech due to swelling of the tongue
- Angioedema
- Accessory muscle use, abnormal respiratory patterns
- Stridor, wheezing, crackles
- Weak or absent radial pulses
- Widespread urticaria and/or pruritus

Reassessment

Reassess en route to the receiving hospital. A patient experiencing a suspected allergic reaction should be monitored with vigilance. Deterioration of the patient's condition can be rapid and fatal, so special attention should be given to any signs of airway compromise. The patient's anxiety level and mental status should be monitored as well because these may provide additional indications of the course of the reaction. Monitor for signs of shock, and, if present, treat immediately.

To treat allergic reactions, you must first identify the severity of the reaction. Mild reactions may only require supportive care and monitoring. On the other hand, anaphylaxis can produce severe or rapidly progressing signs and symptoms, requiring more aggressive treatment, including epinephrine and ventilatory support. In either situation, the patient should be transported to a medical facility for further evaluation.

Recheck your interventions. If you administered epinephrine, what was the effect? Has the patient's condition improved? Does the patient need a second dose? More than one injection of

epinephrine may be appropriate if the patient has decreasing mental status, increased breathing difficulty, or decreasing blood pressure. Remember to consult medical control before administering any subsequent doses for which you have not already obtained authorization.

The point at which you contact medical control depends on your assessment findings and the urgency of care required. In some allergic reactions, you may use standing orders to administer epinephrine before ever calling medical control. At other times, the reaction may be less severe and you may question whether the patient needs an injection of epinephrine. Medical control will be most helpful when the reaction is less severe. Always follow your local protocols.

Words of Wisdom

While one advanced emergency medical technician (AEMT) is getting oxygen ready, the other should be assisting the patient into semi-Fowler position. This positioning will improve perfusion to the brain while easing the patient's respiratory effort.

Your documentation should not only include the signs and symptoms found during your assessment, but should also clearly show care given and *why* you chose to administer the care you provided. If anyone should later question your care, your documentation will show the reasoning for your actions. Finally, be certain to record the patient's response to your treatment.

Emergency Medical Care

You will need to differentiate between anaphylaxis and other conditions with similar symptoms. People who are having allergic reactions are separated into two groups for treatment purposes. The first group includes patients who have signs of an allergic reaction (for example, hives) but no signs of anaphylaxis. The drug of choice in this case is diphenhydramine. Continue to monitor for changes in the patient's condition, but recognize that most patients in this group will recover with no further problems.

The second group includes patients with signs of anaphylaxis. These patients require 100% oxygen, epinephrine, and antihistamines (usually diphenhydramine). Whenever dyspnea and/or signs

YOU are the Provider

Part 4

As your emergency medical technician (EMT) partner returns with the stretcher, you inform him of the patient's worsening condition and indicate that you plan to treat the patient initially on scene before transporting. Because your service carries adult EpiPens, you are able to rapidly administer the epinephrine in his lateral thigh. You also initiate intravenous (IV) access while your partner assembles a handheld nebulizer. Once IV access is established, you establish a line of normal saline at a wide-open rate and administer a 20-mL/kg bolus. After confirming that the patient has no known allergies (other than a possible new penicillin allergy), and following local protocols, you add 2.5 mg of albuterol sulfate to the nebulizer and instruct the patient on its proper use.

Recording Time: 8 Minutes

Respirations	40 breaths/min; severe wheezes bilaterally; audible stridor
Pulse	Absent radial pulses; carotid, 144 beats/min
Skin	Red, swollen patches on torso, extending to arms and legs; seems to be progressing
Blood pressure	72/34 mm Hg
Oxygen saturation (SpO₂)	93% on 100% oxygen

- What will administering albuterol sulfate do to the respirations? What will it do to the patient's oxygen saturation level?
- What is the purpose of the IV fluid bolus?

of shock are present with signs of an allergic reaction, you should administer epinephrine, closely monitor the patient, and provide rapid transport.

Words of Wisdom

Maintain a high index of suspicion if a reaction has occurred previously and the patient has been exposed to the same substance.

If the patient appears to be having a severe allergic or anaphylactic reaction, you should administer basic life support and provide prompt transport to the hospital. When possible, remove the patient from the situation involving the antigen or the antigen from the patient.

Maintain the airway. If the patient is alert, allow the patient to assume a position of comfort that does not compromise breathing. If the patient cannot sit up, have suction readily available to maintain a clear airway. Use an appropriate oxygen delivery device for supplemental oxygen administration and consider early transport. Administer high-flow oxygen via a nonrebreathing mask at 15 L/min if the patient is breathing inadequately and be prepared to assist ventilations. Also, maintain a high index of suspicion for the potential for airway occlusion because of swelling or edema. Consider calling early for advanced life support backup if necessary, treat the patient for shock by placing the patient in the position dictated by local protocol, maintain body heat with a blanket, and initiate IV therapy. IV therapy is discussed in Chapter 13, *Vascular Access and Medication Administration*.

Maintain circulation. Insert at least one large-bore IV catheter of sufficient diameter, such as an 18 gauge, to administer an isotonic solution (lactated Ringer solution or normal saline) at a wide-open rate. Ideally, you should initiate two IV lines en route to the emergency department. This step is crucial, especially if the patient is hypotensive and does not respond to epinephrine. Initially, administer 20 mL/kg of isotonic fluid (normal saline or lactated Ringer) rapidly over 15 minutes intravenously or via intraosseous administration, repeating as needed.⁴ If there is no response, consider calling for paramedic backup if that is an option in your area for administration of a vasopressor in conjunction

with fluid administration. Always monitor patients carefully for the development of pulmonary edema when giving large amounts of fluid.

Special Populations

Because epinephrine can stress the heart, it is important to use this drug only as needed in older patients and patients with a history of cardiovascular disease. Monitor patients closely for cardiac problems or hypertension.

Find out which interventions have been completed before your arrival. Determine whether the patient has any prescribed, preloaded medications for allergic reactions (such as an epinephrine auto-injector), and then inform medical control of the patient's condition.

Words of Wisdom

Whether naturally occurring in the body (endogenous) or made by a drug manufacturer, epinephrine works rapidly to raise the blood pressure by constricting the blood vessels and increasing the strength of cardiac contractions. Epinephrine also dilates the bronchioles, thereby improving the patient's breathing.

- **Indications:** Severe allergic reaction or hypersensitivity to exposed substance or anaphylaxis
- **Contraindications:** None in a life-threatening emergency; however, consult medical control when the patient has a history of heart disease or acute coronary syndrome
- **Actions:** Vasoconstriction and increased cardiac contractility, bronchodilation
- **Side effects:** Tachycardia, sweating, pale skin, dizziness, headache, anxiety, cardiac dysrhythmias
- **Dosage:**
 - Adults: 0.3 to 0.5 mg of a 1-mg/mL (1:1,000) epinephrine solution subcutaneously or intramuscularly (IM)
 - Children: 0.01 mg/kg of a 1-mg/mL (1:1,000) epinephrine solution subcutaneously or IM

Early administration of epinephrine should be a priority. Use the IM route if the patient shows evidence of airway or respiratory compromise or

hypotension. IM administration of epinephrine is preferred for anaphylaxis because it provides more rapid absorption than does subcutaneous administration. Administration in the thigh is preferred over the deltoid site for more rapid absorption. Subcutaneous administration of epinephrine is unpredictable and may have delayed effects in the presence of shock.

Epinephrine is the drug of choice for anaphylactic reactions because its effects are immediate: It can rapidly reverse the histamine-related effects of anaphylaxis. The alpha-adrenergic properties of epinephrine cause the blood vessels to constrict, which reverses vasodilation and hypotension. This elevates the diastolic pressure and improves coronary blood flow. The beta-1 adrenergic effects increase cardiac contractility, reversing the depressing effects on the heart and improving the strength of cardiac contractions. The beta-2 adrenergic effects cause bronchodilation, relieving bronchospasm in the lungs.

Words of Wisdom

The definitive treatment for anaphylaxis is epinephrine!

Many patients and AEMTs carry epinephrine in the form of an EpiPen, so the patient may have administered this medication before your arrival. Patients who receive epinephrine must be monitored closely for adverse effects. Use a cardiac monitor, if available, to watch for dysrhythmias, and reassess the patient's vital signs at least every 5 minutes.

If the patient is able to use the auto-injector without assistance, your role is limited to helping the patient do so. To use, or help the patient use, the auto-injector, you should first receive a direct order from medical control or follow local protocol. Follow standard precautions, and make sure the medication has been prescribed specifically for that patient. If it is discolored or has expired, do not give the medication.

Follow the steps in **SKILL DRILL 22-1** to use an EpiPen auto-injector. In a life-threatening situation, do not delay administration of epinephrine to expose the thigh. An EpiPen can be administered directly through clothing. Note that the injection time, which was formerly recommended as 10 seconds,

has been reduced to 3 seconds; also, take steps to ensure the patient's leg does not move during administration. These steps may help decrease the chance of patient harm during the administration process.⁵ See Chapter 13, *Vascular Access and Medication Administration*, for more information on administering a medication from a vial.

After the medication has been administered, properly dispose of the injector in a biohazard container. Record the time and dose, patient's vital signs, and any response to the medication. If there is no improvement after 5 minutes, consider administration of a second dose. You may also need to give more than one injection of epinephrine if the patient displays decreased mental status, increased breathing difficulty, or decreased blood pressure. Be sure to consult medical control first.

Words of Wisdom

The adult EpiPen delivers 0.3 mg of a 1-mg/mL (1:1,000) solution of epinephrine IM. The EpiPen Jr, which contains 0.15 mg of a 0.5-mg/mL (1:2,000) solution, is used for children who weigh less than 33 lb (15 kg).

In addition to the EpiPen, you may also encounter an Auvi-Q epinephrine injector. They are shaped differently than an EpiPen and come in a dose of 0.1 mg for patients who weigh 17 to 33 pounds (7.5 to 15 kg).

Other allergy kits may contain oral or IM antihistamines, agents that block the effect of histamine. These medications work relatively slowly, within several minutes to 1 hour. Because epinephrine can have an effect within 1 minute, it is the primary way to save the life of someone experiencing a severe anaphylactic reaction. However, epinephrine and antihistamines work synergistically, and both play key roles in reversing and stopping the effects of histamine.

Because epinephrine constricts blood vessels, it may cause the patient's blood pressure to increase significantly. Monitor IV fluid administration carefully to prevent inadvertent fluid overload. Other side effects of epinephrine include tachycardia, anxiety, pallor, dizziness, chest pain, headache, nausea, and vomiting. In a life-threatening situation, the administration of epinephrine outweighs

Skill Drill 22-1 Using an EpiPen Auto-injector

Step 1

Remove the auto-injector's safety cap. Expose and quickly wipe the thigh with antiseptic, if time permits.

Step 2

Place the tip of the auto-injector against the lateral part of the thigh. Push the auto-injector firmly against the thigh until a click is heard. Hold it in place until all the medication has been injected (3 seconds). Ensure the patient's leg does not move during administration.

Step 3

Rub the area for 10 seconds.

Courtesy of Rhonda Hunt.

the risk of side effects. However, patients who do not exhibit signs of respiratory compromise or hypotension and do not meet the criteria for a diagnosis of anaphylaxis should not be given epinephrine.

Whether or not your emergency treatment includes epinephrine, you should always provide prompt transport for any patient who is experiencing an allergic reaction or has experienced a poisonous envenomation or bite. Continue to reassess the patient's vital signs en route; remember that signs and symptoms may change rapidly when a patient has an allergic or anaphylactic reaction. If the patient's condition improves, provide supportive care, including continuing oxygen therapy during transport.

Consider early transport or calling for paramedic backup if the patient needs resources beyond your capabilities. Even if you are able to stop the reaction and the patient begins to recover, patients who have had an anaphylactic reaction should be evaluated and be observed in a medical facility. Up to 20% of patients will experience a recurrence of the symptoms within the next 8 hours, even if they have been symptom-free for a time.⁶

Words of Wisdom

Allergic reactions and responses to bites and stings can become rapidly life threatening. With prompt care, severe signs and symptoms may subside just as quickly. Thus, performing a multisystem examination and documenting your findings is important before and after treatment. Give particular attention to the patient's skin condition and to the status of respiratory, circulatory, and mental functions.

TABLE 22-5 summarizes the management of anaphylaxis.

Assessment and Management of Insect Stings

Thousands of people in the United States are stung by insects each year.² Deaths resulting from anaphylactic reactions to stinging insects far outnumber deaths due to snake bites: This type of allergy accounts for approximately 90 to 100 deaths each year in the United States.²

YOU are the Provider

Part 5

After administering epinephrine and albuterol, you note that the patient's work of breathing has decreased, and stridor is no longer present. Mild angioedema is apparent, however, and the wheezing is still present bilaterally. You place the patient on the stretcher, being sure to continue the administration of 100% oxygen, and initiate rapid transport to the hospital, which is 14 minutes away. You note that the patient's blood pressure has increased slightly, but the rash appears to be spreading. You opt to contact medical control because you are concerned that the patient has not responded completely to the administration of the epinephrine. Online medical control orders administration of a second dose of 0.5 mg of a 1-mg/mL (1:1,000) concentration epinephrine subcutaneously. After confirming the order, you draw up 0.5 mg of epinephrine and administer it to the patient. After several minutes, you note that the rash appears to be decreasing, and the patient states that he does not itch as badly anymore. His respirations are regular with equal chest rise and no accessory muscle use.

Recording Time: 18 Minutes

Respirations	24 breaths/min; clear bilaterally
Pulse	Strong distal pulse; 92 beats/min
Skin	Small area of redness on anterior torso; area appears to be decreasing
Blood pressure	104/72 mm Hg
Oxygen saturation (SpO₂)	98% on 100% oxygen

You continue monitoring the patient en route to the hospital. On arrival, you give your report to the emergency department nurse and complete your patient care report while your partner readies the ambulance for your next call.

- What are some possible side effects of epinephrine administration?

TABLE 22-5 Management of Anaphylaxis

- Remove the offending agent.
- Position the patient as appropriate.
- Apply high-flow oxygen, or assist ventilation as needed.
- Obtain IV access.
- Give fluid resuscitation as needed.
- Administer epinephrine and an antihistamine (eg, diphenhydramine) as indicated.
- Transport promptly.
- Frequently reassess the patient, and provide psychological support.

FIGURE 22-4 Most stinging insects inject venom through a small, hollow spine that projects from the abdomen.

A. The stinger of the honeybee is barbed; the honeybee cannot withdraw its stinger once it has stung someone.

B. The wasp's stinger is not barbed, meaning that it can inflict multiple stings.

A: © manfredxy/Shutterstock; **B:** © Heintje Joseph T. Lee/Shutterstock.

The stinging organ of most bees, wasps, and hornets is a small, hollow spine projecting from the abdomen. Venom can be injected through this spine directly into the skin. The stinger of the honeybee is barbed, so the bee cannot withdraw it (**FIGURE 22-4A**). Instead, the bee leaves a part of its abdomen embedded with the stinger and dies shortly after flying away. In contrast, wasps and hornets do not have this handicap; they can sting repeatedly (**FIGURE 22-4B**). Because these insects usually fly away after stinging, it is often

A

B

FIGURE 22-5 A. The fire ant. **B.** Fire ants inject an irritating toxin at multiple sites. Bites are generally found on the feet and the legs and appear as multiple small, raised pustules.

A: Courtesy of Scott Bauer/USDA; **B:** © Scott Camazine/Alamy.

impossible to identify which species was responsible for the injury.

Some ants, especially the fire ant (*Solenopsis*), also strike repeatedly, injecting a particularly irritating **toxin**, or poison, at the bite sites (**FIGURE 22-5A**). It is not uncommon for a patient to rapidly sustain multiple ant bites, usually on the feet and legs (**FIGURE 22-5B**).

Signs and symptoms of insect stings and bites include sudden pain, swelling, localized heat, widespread urticaria, and redness in light-skinned

people, usually at the site of injury. There may be itching and sometimes a **wheel**, which is a raised, swollen, well-defined area on the skin (**FIGURE 22-6**). Applying ice sometimes makes wheals less irritating. The swelling associated with an insect bite may be dramatic and sometimes frightening to the patient or to you. However, as long as these manifestations remain localized, they are not usually serious.

Because the stinger of a honeybee remains in the wound created by its sting, it can continue to inject venom for up to 20 minutes following the actual sting. Thus, if the stinger is still in place, attempt to remove the stinger by scraping the skin with the edge of a sharp, stiff object such as a credit card (**FIGURE 22-7**). Do not use tweezers or forceps to remove the stinger because this may squeeze more venom into the wound.

FIGURE 22-6 A wheal is a white, firm elevation of the skin that occurs after an insect sting or bite.

© Simon Krzic/Shutterstock.

FIGURE 22-7 To remove the stinger of a honeybee, gently scrape the skin with the edge of a sharp, stiff object such as a credit card.

© Jones & Bartlett Learning.

Gently wash the area of the insect sting with soap and water or a mild antiseptic. Try to remove any jewelry from the area before swelling begins. Position the injection site slightly below the level of the heart and apply ice or cold packs to the area. Placing ice over the injury site may slow absorption of the toxin, diminish swelling, and relieve pain.

Be alert for signs of airway swelling and other signs of anaphylaxis such as nausea, vomiting, and abdominal cramps, and do not give the patient anything by mouth. Place the patient in the supine position if indicated and give oxygen if needed. Monitor the patient's vital signs, and be prepared to provide further support as needed.

Patient Education

The best management of anaphylaxis and allergic reactions is to educate patients about prevention and self-preservation. At a minimum, discuss the following topics:

- **Avoid the antigen.** Review information on the offending item. For example, patients who are allergic to penicillin should be provided with a list of drugs that include penicillin and the alternative names for penicillin. Drugs that may produce a cross-reaction should also be discussed. Food allergies can be even more difficult to avoid. For example, peanuts can be found in many other foods: Peanut oil may be used to prepare foods that do not actually contain peanuts, and peanut butter may be an ingredient in various foods. Some patients are so allergic to peanuts that just using the same devices to process non-peanut-containing foods can cause a reaction. Patients must be educated to avoid the allergen, read labels, and ask about how food is prepared to avoid exposure. Latex allergies are also a concern, so advising patients to notify care providers of latex allergies is essential. Many services are latex-free, but not all of them, so patients must inform providers of their allergies so exposures can be avoided.
- **Notify all health personnel of the allergy.** Review the need to alert health personnel to the allergy. This step is important because patients often think only a physician would need this information, not an emergency medical services (EMS) provider.

- **Wear identification tags or bracelets.** These items notify providers of allergies in case the patient is unable to do so.
- **Carry an anaphylaxis kit or EpiPen.** A reaction may occur rapidly or worsen before help can arrive. Make sure the patient and family know how to use the kit or EpiPen.
- **Report symptoms early.** Ideally, interventions should begin before the situation becomes life threatening. The patient should recognize that reactions can occur more rapidly and with greater severity with repeated exposures.

YOU are the Provider SUMMARY

1. What is the major difference between an allergic reaction and anaphylaxis?

The major difference between an allergic reaction and anaphylaxis is that an allergic reaction is more of an “annoyance,” whereas anaphylaxis is a potentially life-threatening problem. Anaphylaxis typically involves two or more organ systems, whereas an allergic reaction typically involves only one system.

2. How are the treatments for these two conditions the same? How do they differ?

Treatment for an allergic reaction is typically supportive. The signs and symptoms can usually be relieved by supplemental oxygen to decrease anxiety and administration of an antihistamine, such as diphenhydramine, to decrease the size and intensity of the rash. Anaphylaxis typically involves the airway, causing stridor or bronchospasm. These effects can be relieved by administration of medication by an inhaled bronchodilator, such as albuterol sulfate. Epinephrine may need to be administered to attempt to cause vasoconstriction and improve contractility, thereby increasing the blood pressure, and to ensure bronchodilation.

3. What is the significance of stridor not being present during airway assessment?

Stridor indicates an upper airway obstruction due to swelling, which, in this patient, is not present yet. Because stridor is absent, you can assume that the patient currently has a patent airway.

4. In which position should this patient be placed?

This patient should be placed in the position of comfort. Any position that maximizes oxygenation and ventilation, while minimizing anxiety, should be considered.

5. Based on his presentation, what is the definitive treatment for this patient?

The patient is showing signs of respiratory and cardiovascular compromise indicating anaphylaxis. Epinephrine is the definitive treatment for anaphylaxis.

6. What will administering albuterol sulfate do to the respirations? What will it do to the patient's oxygen saturation level?

The administration of albuterol sulfate may initially cause the patient's respirations to increase; this patient already has increased work of breathing and will be attempting to get the medication into his respiratory tract to alleviate the respiratory distress more quickly. However, once the albuterol sulfate begins to work by dilating the bronchioles, the patient's respirations will decrease and his oxygen saturation level will increase.

7. What is the purpose of the IV fluid bolus?

The IV fluid bolus is intended to maintain circulation. Insert at least one large-bore IV catheter to administer an isotonic solution (lactated Ringer solution or normal saline) at a wide-open rate. Ideally, you should place two IV lines en route to the emergency department. This step is crucial, especially if the patient is hypotensive and does not respond to the epinephrine. Initially, a 20-mL/kg bolus should be administered. If there is no response, contact medical control prior to administering more fluid, and consider paramedic rendezvous or backup.

8. What are some possible side effects of epinephrine administration?

Common side effects of epinephrine are tachycardia, palpitations, sweating, pale skin, headache, anxiety, dizziness, and cardiac dysrhythmias.

Narrative

EMS called to above location for a 46 y/o male with a possible allergic reaction. On arrival, patient found seated on sofa, AO × 4, but anxious. Patient presents with mild respiratory distress, absent peripheral pulses, and mottled skin. Patient states that he had a doctor's appointment this morning and his physician prescribed a new medication, penicillin. Patient states that he has never taken this medication before, and took it approximately 1 hour ago. Approximately 30 minutes later, a large rash developed on anterior part of torso, with profuse itching. Patient presents with increased work of breathing, progression of rash, and audible stridor. Supplemental oxygen applied via nonrebreathing mask at 15 L/min. 0.3 mg of 1 mg/mL (1:1,000) epinephrine administered IM to right lateral thigh, 2.5 mg albuterol sulfate administered via nebulizer, and 18-gauge IV line established in left AC, with 20-mL/kg bolus of normal saline initiated. After administration of medications, patient presents with decreased work of breathing, no stridor, and diminished areas of rash. Patient assisted to stretcher and secured in position of comfort. Transported nonemergency to North Keen Medical Center. En route, patient has increasing angioedema and wheezing, and rash continues to spread. Per medical control, second dose of 0.5 mg of 1 mg/mL (1:1,000) epinephrine for progressing anaphylaxis given subcutaneously in left forearm. On reassessment, patient began showing marked improvement in signs and symptoms, with wheezing decreased and size of rash shrinking. Report called to emergency department with condition and ETA. On arrival, care transferred and report given to nurse without incident.

End of report

Prep Kit

Ready for Review

- An allergic reaction is a response to chemicals the body releases to combat certain stimuli, called *allergens*. Almost any substance can trigger the body's immune system and cause an allergic reaction. Allergic reactions occur most often in response to five categories of stimuli: insect bites and stings, medications, foods, plants, and chemicals.
- Anaphylaxis is a life-threatening allergic reaction mounted by multiple organ systems that must be treated with epinephrine. Wheezing and skin wheals can be signs of anaphylaxis.
- The immune system protects the human body from substances and organisms that are considered foreign to the body.
- Allergens enter the body through oral ingestion, injection or envenomation, inhalation, or topical absorption. Injected and inhaled allergens tend to cause the most severe reactions, but a severe reaction can occur by any route.
- When a foreign substance first invades the body, the primary response begins. If the body is unable to identify the substance, immune cells record the features of the outside substance and produce antibodies to inactivate the foreign substance. This process is called *development of sensitivity*.
- Basophils and mast cells contain antibodies and can recognize the foreign substance should it enter the body again. Basophils are stationed in specific sites within the tissues. Mast cells are on patrol throughout the body.
- Chemical mediators are essentially the body's weapons against foreign substances. They release substances when an antigen invades the body and combines with one of the antibodies. If this response spreads throughout the body (becoming systemic), it causes the signs and symptoms of an anaphylactic reaction. Allergic reactions are more localized.
- Histamine is one of the primary chemical mediators. It causes the blood vessels in the local area to dilate and the capillaries to leak; this translates into flushed skin, hypotension, tissue swelling, and fluid secretion.
- Other chemical mediators include the leukotrienes, which cause additional dilation and leaking of fluid into the tissues.
- Signs and symptoms of an anaphylactic or allergic reaction vary but can include hives, pruritus (itching), flushed skin, swelling, respiratory symptoms (wheezing, stridor, dyspnea, and angioedema), cardiovascular symptoms, gastrointestinal symptoms, neurologic symptoms, and even shock if the reaction is severe.
- When assessing a person who may be having an allergic reaction, check for flushing, itching, and swelling skin; hives; wheezing and stridor; a persistent cough; a decrease in blood pressure; a weak pulse; dizziness; abdominal cramps; and headache.
- The patient history will help to identify problems specific to the allergic reaction. When assessing a patient with an allergic reaction, ask if the patient has a history of allergies, what the patient was exposed to, when the exposure occurred, and how the patient was exposed. Determine the onset of symptoms, the effects of the exposure, and the progression of those effects.
- The airway is always a priority in every situation, and assessing for the presence of stridor and hoarseness should indicate the severity of the airway compromise in a patient with an anaphylactic or allergic reaction. All patients with suspected anaphylaxis require oxygen.
- People who know that they are allergic to bee, hornet, yellow jacket, or wasp venom often carry a bee sting kit that contains epinephrine in an auto-injector. You may help to administer

this medication in this form with authorization from medical control.

- Always provide prompt transport to the hospital for any patient who is having an allergic reaction or has been bitten by a venomous insect. Remember that the patient's condition can deteriorate rapidly. Carefully monitor the patient's vital signs en route, especially for airway compromise.
- Patients having allergic reactions are separated into two groups for treatment purposes. Those with signs and symptoms of an allergic reaction but no signs of anaphylaxis should be treated with diphenhydramine. Those with signs of

anaphylaxis require 100% oxygen, epinephrine, and antihistamines. Early administration of epinephrine should be a priority.

- Management also includes removing the offending agent, providing fluid resuscitation as needed, and transporting promptly.
- Patient education related to anaphylaxis and allergic reactions includes the following points:
 - Avoid the antigen.
 - Notify all health personnel of the allergy.
 - Wear identification tags or bracelets.
 - Carry an anaphylaxis kit or EpiPen.
 - Report symptoms early.

Vital Vocabulary

absorption In pharmacology, the process by which medications travel through body tissues until they reach the bloodstream; in allergic reactions, when foreign material is deposited on and moves into the skin.

acquired immunity The immunity that occurs when the body is exposed to a foreign substance, antigen, or disease, and produces antibodies to the invader.

allergen A substance that causes an allergic reaction.

allergic reaction The body's exaggerated immune response to an internal or a surface antigen.

anaphylactoid reaction An extreme allergic response that does not involve IgE antibody mediation. The exact mechanism is unknown, but an anaphylactoid event may occur without the patient being previously exposed to the offending agent.

anaphylaxis An extreme, life-threatening, systemic allergic reaction to foreign protein or other substances, which may include shock and respiratory failure.

angioedema Recurrent large areas of subcutaneous edema of sudden onset, often around the

eyes and lips and usually disappearing within 24 hours, which is seen mainly in young women, frequently as a result of allergy to food or drugs.

antibody A protein secreted by certain immune cells that bind antigens to make them more visible to the immune system; an immunoglobulin.

antigen An agent that, when taken into the body, stimulates the formation of specific protective proteins called antibodies.

basophils White blood cells that work to produce chemical mediators during an immune response.

cellular immunity The immunity provided by special white blood cells called T cells that attack and destroy invaders.

chemical mediators Chemicals that work to cause the immune or allergic response—for example, histamine and leukotrienes.

envenomation The act of injecting venom.

epinephrine A substance produced by the body (commonly called adrenaline), and a drug produced by pharmaceutical companies that increases pulse rate and blood pressure; the drug of choice for treating an anaphylactic reaction.

histamine Chemical substance released by the immune system in allergic reactions that is

responsible for many of the symptoms of anaphylaxis, such as vasodilation; increases vascular permeability and tissue inflammation; found in large amounts in basophils.

humoral immunity A type of immunity in which B cell lymphocytes produce antibodies called immunoglobulins, which recognize a specific antigen and then react with it.

hypersensitivity Abnormal sensitivity; a condition in which the body manifests an exaggerated response to the stimulus of a foreign agent.

immune system The body system that includes all of the structures and processes designed to mount a defense against foreign substances and disease-causing agents.

immunity In medicine, the body's ability to protect itself from acquiring a disease; in a legal context, legal protection from penalties that could normally be incurred under the law.

ingestion Eating or drinking materials for absorption through the gastrointestinal tract.

inhalation The active, muscular part of breathing that draws air into the airway and lungs; a medication delivery route; in allergic reactions, breathing in foreign substances through the respiratory system.

injection In allergic reactions, piercing of the skin, followed by deposition of foreign material into the skin.

leukotrienes Arachidonic acid metabolites that function as chemical mediators of inflammation; released by the immune system in allergic reactions; also known as slow-reacting substances of anaphylaxis.

local reaction A mild or moderate allergic reaction that the body limits to a specific area after being exposed to a foreign substance.

mast cells Cells located in the tissues that release chemical mediators in response to an antigen-antibody reaction.

natural immunity A nonspecific cellular and humoral response that operates as the body's first line of defense against pathogens; this develops as part of being exposed to an antigen and developing antibodies; also called native immunity.

primary response The first encounter with the foreign substance that initiates the immune response.

pruritus Itching.

secondary response The body's reaction when it is exposed to an antigen for which it already has antibodies, in which it responds by killing the invading substance.

sensitivity The ability of the body to recognize a foreign substance the next time it is encountered.

stridor A harsh, high-pitched breath sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

systemic reaction A reaction that occurs throughout the body, possibly affecting multiple body systems.

toxin A poison or harmful substance produced by bacteria, animals, or plants.

urticaria Small areas of generalized itching and/or burning that appear as multiple raised areas on the skin; hives. May be one of the warning signs of impending anaphylaxis.

wheal A raised, swollen, well-defined area on the skin resulting from an insect bite or allergic reaction.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Chapter 23

Toxicology

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Toxicology

Recognition and management of

- Carbon monoxide poisoning (pp 1140, 1164)
- Nerve agent poisoning (p 1164)

How and when to contact a poison control center (p 1139)

Anatomy, physiology, pathophysiology, assessment, and management of

- Inhaled poisons (pp 1140–1141)
- Ingested poisons (pp 1139–1140)
- Injected poisons (pp 1141–1142)
- Absorbed poisons (pp 1142–1143)
- Alcohol intoxication and withdrawal (pp 1151–1153)
- Opioid toxidrome (pp 1153–1155)

KNOWLEDGE OBJECTIVES

1. Define the terms toxicology, poison, and overdose. (p 1138)
2. Describe the routes by which poisons are absorbed in the body. (pp 1139–1143)
3. Discuss major toxidromes and their use in assessment and management of toxicologic emergencies. (p 1143)
4. Identify the common signs and symptoms of poisoning. (p 1144)
5. Discuss substance abuse and concepts associated with it. (pp 1143, 1145–1146)
6. Describe the assessment and treatment of a patient with suspected poisoning. (pp 1146–1147)
7. Describe the assessment and treatment of a patient with a possible overdose. (pp 1147–1148)
8. Understand the role of airway management in a patient with poisoning or overdose. (pp 1148–1150)
9. Explain the use of activated charcoal, including indications, contraindications, and the need to obtain approval from medical control before its administration. (pp 1150–1151)
10. Discuss emergencies related to severe intoxication, including alcoholism. (p 1151)
11. Explain the effects of each of the specific types of poisons: alcohol, opioids, stimulants, marijuana, hallucinogens, sedative-hypnotic drugs, cardiac medications, other medications, organophosphates, inhalants, metals, and caustics. (pp 1151–1166)
12. Describe the assessment and treatment for the patient with suspected food poisoning. (p 1169)
13. Describe the assessment and treatment for the patient with suspected plant poisoning. (pp 1169–1171)

SKILLS OBJECTIVES

1. Demonstrate the steps in the assessment and treatment of the patient with suspected poisoning. (p 1146)
2. Demonstrate the steps in the assessment and treatment of the patient with suspected overdose. (pp 1148–1149)
3. Demonstrate the steps required to administer activated charcoal. (pp 1150–1151)

Introduction

In the course of their duties, advanced emergency medical technicians (AEMTs) treat patients who have taken drugs of abuse (including alcohol) on an almost daily basis. Given the nature of drug use and abuse, it is impossible to accurately identify how many users of such substances exist. Sometimes the abused substance is legal (**licit**), as in the case of alcohol and oxycodone (when the patient has a prescription). At other times, the substance is illegal (**illicit**), as in the case of heroin and ecstasy.

Before delving into this challenging area of AEMT practice in depth, it is important to define some key terms. A **poison** is a substance that is toxic by nature, no matter how it gets into the body or in which quantity it is taken. At a minimum, a poison has the potential to make people ill; in the worst-case scenario, it will kill them. By contrast, a **drug** is a substance that has a physiologic effect when given in the appropriate circumstances and in the appropriate dose. For example, a drug may reduce inflammation, fight bacteria, or produce euphoria. (A medication refers to a substance used to treat an illness or medical condition.) When a drug (licit or illicit) is taken in excess, the person is said to have overdosed; an **overdose** is a toxicologic emergency, because the person has been poisoned. In a nutshell, a poison is always a poison, whereas a licit or illicit substance can poison a person if it is taken to excess.

Types of Toxicologic Emergencies

Toxicology is the study of toxic or poisonous substances. **Toxicologic emergencies** usually fall under one of two general headings: intentional or unintentional. Poisoning in adults is commonly intentional.

An unintentional toxicologic emergency can occur in many ways. For example, medication dosing errors are common problems in clinical practice. In

some cases, the event may be idiosyncratic: 2 mg of midazolam (Versed) may relax one patient but cause respiratory arrest in another person.

Childhood poisonings are common, especially in young children. Young children may put anything into their mouths, such as colorful berries found on a house or garden plant that draw their attention. In addition, a parent's prescription medication may be mistaken for candy.

Nature is fraught with toxicologic perils. For example, wild mushrooms, once ingested, can produce a wide spectrum of reactions, from nausea to death.

The workplace also harbors its share of toxic hazards. Unfortunately, some of these hazards are not identified until after an exposure has occurred. For example, countless people who worked with polychlorinated biphenyls (PCBs) on a daily basis in the electric energy field developed cancer later in life; only then was the harmful nature of PCBs recognized. Similarly, thousands of people developed asbestosis after continued exposure to asbestos in the workplace, and their illnesses prompted research that identified the true toxicity of this material.

Sometimes unintentional toxicologic emergencies may occur as a result of simple neglect or oversight. For example, a geriatric person with diabetes and comorbid early-onset dementia or Alzheimer disease may take insulin in the morning, but later be unable to remember whether the dose was taken. If the patient then takes another dose, the result may be a call to 9-1-1 for an unresponsive person in need of assistance.

The risks associated with chemical and biologic warfare have drawn increasing attention in recent years owing to the heightened awareness of bioterrorism, but intentional poisoning or overdose more commonly occurs during much smaller-scale crimes. In recent years, date rape drugs such as flunitrazepam (Rohypnol) have been used to facilitate sexual assault. Chloral hydrate ("knockout

drops”) has been used to commit assault for decades, and pharmacologic agents are used in homicides as well.

Poison Centers

Given the wide variety of illicit drugs, coupled with the continued growth in the number of licit drugs, even the most well-read veteran AEMT may find it difficult to keep up-to-date on the myriad drugs sold in the streets today. For this reason, the American Association of Poison Control Centers’ Poison Help line (1-800-222-1222) may be an indispensable aid in a suspected toxicologic emergency.¹

Suppose you are called to a home where a frantic mother is hovering over a toddler who sits beside the remains of a planted philodendron, most of which he apparently just ate. Is the plant poisonous? How poisonous? Should you make the child vomit? Is an antidote available? In such a scenario, you can call a poison center and get a fast rundown on the ingestion, its toxic potential, and steps to negate its effects, thereby providing proper patient care.

Poison centers have access to information about almost all commonly used medications, chemicals, and substances that could possibly be poisonous. Never hesitate to use these resources when confronted with a call involving *any* toxin (poison) with which you have limited or no familiarity. In addition to assisting with the current incident, your call helps the center collect data on poisonings in your region. These data are analyzed to help detect trends, identify developing public health problems, and evaluate current treatment protocols for different poisonings.

Some mobile medical reference apps, such as Epocrates, will assist with pill identification. You input basic information about the pills (shape, color, or markings), and the software identifies a list of potential medications. Poison Control also offers an online triage tool and mobile device app called webPOISONCONTROL that can be used by laypeople or health care providers.

Pathophysiology: Routes of Absorption

Toxins cannot exert their effects until they enter the human body. The four primary methods of entry are ingestion, inhalation, injection, and absorption. Just as each of these methods of entry is unique, so is the rate at which a given toxin is absorbed into the body by that route. Once a toxin is in the body, the combination of the amount of toxin and the relative speed at which it is metabolized determine its effects and excretion rate.

Poisoning by Ingestion

Medications around the home and household chemicals (such as cleaning agents or laundry detergent capsules) are the most common sources of poisoning by ingestion. Ingested poisons may produce immediate damage to tissues, or their toxic effects may be delayed for several hours. With ingestion of a caustic substance (ie, a strong acid or alkali), these effects occur immediately. By contrast, some poisons must be absorbed into the bloodstream before they will produce toxic effects.

Assessment clues pointing toward ingestion can be as obvious as a plant with partially chewed leaves

YOU are the Provider

Part 1

You and your partner are dispatched to assist local law enforcement officers with an unknown medical problem. When you arrive on scene, you note the presence of four police cars in the immediate vicinity, increasing your index of suspicion for violence. A police captain approaches your ambulance and tells you that police were called to the location for a “person acting strange.” When the first officer arrived, she found a naked man standing in the front yard of a residence, with both arms bloodied, screaming unintelligible words. Officers have tried to calm the man, but he refuses to comply with their commands, and the captain states that they are trying to decide on the best way to subdue him.

1. What are the potential hazards with this scene?
2. What is a likely explanation for this patient’s presentation?

or a section of a plant with berries missing. Stained fingers, lips, or tongue are other indicators of ingestion. Any patient complaining of a sudden onset of stomach cramps with or without nausea, vomiting, or diarrhea may have an ingestion-related problem. Empty pill bottles are another obvious clue, as is the date on which the prescription was filled. The bottle for a prescription filled 6 months ago is not likely to be full today; an empty bottle for a prescription filled yesterday is far more ominous.

Entry of a toxin into the body by the oral route generally provides a more forgiving time frame for treatment. Little absorption occurs in the stomach; indeed, the ingested substance may stay there for a variable period, with most absorption actually occurring in the small intestine. Consequently, managing poisoning by ingestion should focus on removing or neutralizing the poison before it enters the patient's intestines.

In specific ingestion emergencies, some emergency medical service (EMS) systems may allow AEMTs to use activated charcoal as an alternative treatment (**FIGURE 23-1**). Activated charcoal, which comes as a suspension, binds to the poison in the stomach and carries it out of the patient's system. Because of this mechanism of action, it is more effective and safer for patients than syrup of ipecac. However, its administration is associated with the

FIGURE 23-1 Activated charcoal comes as a premixed suspension that you should administer, if local protocol allows, in a covered cup with a straw.

© Charles Stewart MD, EMDM MPH.

risk of severe pulmonary injury if aspirated. Administration of activated charcoal is discussed later in this chapter.

As always, you should immediately assess the airway, breathing, and circulation (ABCs) of a patient with suspected poisoning. Many patients have died as a result of problems with their ABCs that might have been managed easily. Provide aggressive ventilatory support and cardiopulmonary resuscitation (CPR) to a patient who has ingested an opioid, a sedative, or a barbiturate, as all of these types of drugs can cause depression of the central nervous system (CNS) and slow breathing.

Whenever ingestion poisoning is suspected, you should provide prompt transport to the emergency department (ED). The patient may need intravenous (IV) support and may require other treatments that can be given only in the hospital.

Words of Wisdom

As e-cigarettes have gained popularity due to their low cost, flavored options, and approved use indoors (in some places), they have become an emerging source of poisonings. The liquid nicotine contained in an e-cigarette is often the offending agent. The most common route of exposure is inhalation, but there are reported cases of ingestion and absorption through the eyes.² Nausea, vomiting, and eye irritation are common symptoms following an exposure.³ Pediatric exposures have also increased further, conveying the need to keep e-cigarettes out of the reach of children.³

Poisoning by Inhalation

Home medications and household chemical products (such as bleach and cleaning agents) are responsible for the most common types of inhalation emergencies. A person can be poisoned by inhalation only if the poison is present in the surrounding atmosphere. That fact has important implications. First, so long as the patient remains in the toxic environment, the person will keep inhaling the poison—and so will you. For example, **carbon monoxide (CO)**, an odorless, colorless, tasteless, and highly poisonous gas, is a hazard for rescuers as well as for patients. Therefore, you should not enter the hazardous environment; instead, call for additional responders with specialized protective equipment. Second, when poisoning occurs because of a toxic

environment, you are likely to encounter more than one patient at the emergency scene.

Inhaled toxins quickly reach the alveoli, which then allow the toxins almost instant access to the circulation. Carbon monoxide molecules, for example, bind to hemoglobin on the red blood cells 200 to 250 times more readily than do oxygen molecules, which leads to rapidly diminished oxygen-carrying capacity. In turn, patients experience a rapid onset of signs and symptoms. For this reason, the window of opportunity for treating an inhalation poisoning is limited.

When you are dealing with an inhalation emergency, the first general management consideration is to ensure scene safety. Specialized personnel will likely need to access the patient, and the patient may need to be decontaminated by special rescuers after removal from the toxic environment. Consult with poison control or local hazardous materials team members regarding the need for patient decontamination. Remove the patient's clothing in this process because it may contain trapped gases that can be released later, thereby exposing you or other responders to the toxin. Do not administer emergency care until this step has been completed and there is no danger of the poison contaminating you.

Safety

Never pull a shirt over the head of a patient who may have been exposed to a toxin. Doing so may introduce the toxin into the patient's eyes, nose, or mouth. Instead, unbutton or cut the shirt to remove it. Pulling clothing over a patient's head could also introduce the toxin into the air, causing a hazard to you or other providers.

Inhaled toxins produce a wide range of signs and symptoms, many of which are unique to the toxin involved. For example, a patient with CO poisoning does not exhibit the same signs and symptoms as a person who has sniffed glue, who in turn looks nothing like a patient poisoned by a furniture stripper containing methylene chloride.

As with other types of poisoning, it is helpful to take any suspicious containers, bottles, and labels with you, or pictures of them, when you transport the patient with inhalation poisoning to the hospital. Often patients use inhaled poisons to commit

suicide, such as when a person sits inside a vehicle with the engine running in an enclosed garage. The exhaust fumes from the vehicle contain high levels of CO that will cause the patient to lose consciousness and eventually stop breathing. A recent variation on the use of automobiles for suicide, called **chemical suicide**, involves people using a tightly sealed vehicle as a type of gas chamber. Fairly common household chemicals are mixed inside the vehicle to produce hydrogen sulfide gas, which is quickly fatal. When you approach such a vehicle and open the door, you may be overcome by the gas as well. Signs of chemical suicide include taped or sealed windows, locked doors, posted warning signs, a suicide note, empty chemical containers, and unusual odor. If you suspect this type of poisoning has taken place, contact hazardous materials responders and have them remove the patient from the vehicle.

Frequently, the emergency scene itself provides clues about the identity of the toxin. That information, coupled with the assistance of the poison center and direction from the medical control physician, will drive your treatment plan. You must treat hypoxia immediately, so administer a high concentration of oxygen. Establish vascular access and perform pulse oximetry. Call early for paramedic backup.

Words of Wisdom

Always treat the patient, rather than the diagnostic tool. Pulse oximeters, for example, are notorious for giving false readings when patients have been exposed to many chemicals, including carbon monoxide and cyanide. Administer oxygen as appropriate without regard to pulse oximetry readings if the patient has difficulty breathing.

Poisoning by Injection

Poisoning by injection is usually the result of drug abuse, such as with heroin or cocaine.

Depending on the specific toxin injected, signs and symptoms can vary greatly. Frequently, the patient may be able to identify the source, greatly simplifying the assessment process.

In general, injected poisons are impossible to dilute or remove because they are usually absorbed

quickly into the body or cause intense local tissue destruction. If you suspect that rapid absorption has occurred, monitor the patient's airway, administer high-flow oxygen, and be alert for nausea and vomiting. Remove rings, watches, and bracelets from areas around the injection site if swelling occurs. Prompt transport to the ED is essential. Take all containers, bottles, and labels with the patient to the hospital.

Bites and stings are also considered to be a form of poisoning by injection. Managing specific bites and stings is covered in Chapter 22, *Immunologic Emergencies*, and Chapter 34, *Environmental Emergencies*.

Poisoning by Absorption

Some poisons gain access to the body by being absorbed through the skin. Of the various poisonings that occur by absorption, those caused by pesticides such as organophosphates and similar substances are often the most serious.

Many corrosive substances will damage the skin, mucous membranes, or eyes, causing chemical burns, telltale rashes, or lesions. For example, acids, alkalis, and some petroleum (hydrocarbon) products have very destructive local effects. Other substances are absorbed into the bloodstream through the skin and have systemic effects. Still other substances, such as poison ivy or poison oak, may just cause an itchy rash without being dangerous to the patient's health. It is important, therefore, to distinguish between contact burns and contact absorption.

Words of Wisdom

Absorption of toxic substances through the skin is a common problem in agriculture and manufacturing. Most solvents and "cides" (insecticides, herbicides, and pesticides) are toxic and can be readily absorbed through the skin.

Signs and symptoms of absorption poisoning include a history of exposure, liquid or powder on a patient's skin, burns, itching, irritation, redness of the skin in light-skinned people, or typical odors of the substance.

As always, emergency medical treatment for a typical contact poisoning begins with avoiding contamination for both yourself and others. Once you

accomplish this step and you protect yourself from exposure, remove the irritating or corrosive substance from the patient as rapidly as possible. Cut off all clothing that has been contaminated with poisons or irritating substances. Never pull clothing over a patient's head; doing so could introduce the material into the eyes, nose, and mouth. Note that the order of these steps is important. You should never flush off a dry powder, as that could activate a chemical reaction. First, thoroughly brush the dry powder off; next, flush the skin with running water; and then, wash the skin with soap and water. When a large amount of material has been spilled on a patient, flooding the affected part for at least 20 minutes may be the fastest and most effective treatment.

If the patient has a chemical agent in the eyes, irrigate the eyes quickly and thoroughly. To avoid contaminating the other eye as you irrigate the affected eye, ensure the fluid runs from the bridge of the nose outward (**FIGURE 23-2**). This action should be started initially on the scene and continued during transport.

Many chemical burns occur in industrial settings, where showers and specific protocols for handling surface burns are available. If you are called to such a scene, trained people usually will be there to assist you. Do not spend time trying to neutralize substances on the skin with additional chemicals, as this action may be more harmful than leaving the original chemical intact. Instead, brush off as much as possible if the material is a solid, and then

FIGURE 23-2 If chemical agents are in the patient's eyes, then irrigate the eyes quickly and thoroughly, ensuring that the irrigation fluid runs from the bridge of the nose outward. (Use of a nasal cannula is pictured.)

© American Academy of Orthopaedic Surgeons.

immediately wash off the substance with plenty of water. Obtain material safety data sheets from industrial sites and transport them with the patient, if available.

The only time you should not irrigate the contact area with water after brushing it off is when a patient has been contaminated with a poison that reacts violently with water, such as phosphorus or elemental sodium. These substances ignite when they come in contact with water. In such a case, you should brush off the chemical from the patient, remove contaminated clothing, and apply a dry dressing to the burn area. Ensure you wear appropriate protective gloves and the proper protective clothing when performing these steps.

For all patients with absorption poisoning, provide prompt transport to the ED for definitive care. En route, continue irrigation and administer oxygen if possible.

Understanding and Using Toxidromes

Although the sheer number of substances of abuse may seem daunting, the good news is that many drugs, on entering the body, result in similar signs

and symptoms. For example, whether an opioid is a natural product derived from opium (eg, heroin) or a synthetic, non-opium-derived substance (eg, fentanyl), all drugs in this group work in a similar manner, so they produce similar signs and symptoms. The syndromelike symptoms of a poisonous agent are termed a toxic syndrome or **toxidrome**. Toxidromes are useful for remembering the elements in assessing and managing different substances that fall under the same clinical umbrella. The major toxidromes are produced by stimulants, opioids, sympathomimetics, sedatives and hypnotics, cholinergics, and anticholinergics (**TABLE 23-1**).

TABLE 23-2 lists common signs and symptoms of poisoning. If you look at the patient's history and physical examination findings in conjunction with the vital signs, you can often develop a working diagnosis that will allow you to provide appropriate care until the patient reaches the receiving facility.

Overview of Substance Abuse

The area of medicine dealing with drugs of abuse is highly challenging because of uncertainty about the prevalence of the problem and the continual

TABLE 23-1 Major Toxidromes	
Toxidrome	Signs and Symptoms
Stimulant (Examples: amphetamine, methamphetamine, cocaine, diet aids, nasal decongestants)	Restlessness, agitation, incessant talking, insomnia, anorexia, dilated pupils, tachycardia, tachypnea, hypertension or hypotension, paranoia, seizures, cardiac arrest
Opioid (Examples: heroin, morphine, hydromorphone [Dilaudid], fentanyl, oxycodone)	Pinpoint pupils, marked respiratory depression, drowsiness, stupor, coma
Sympathomimetic (Examples: epinephrine, albuterol, cocaine, methamphetamine)	Hypertension, tachycardia, dilated pupils, agitation and seizures, hyperthermia
Sedative-hypnotic (Examples: diazepam [Valium], secobarbital [Seconal], flunitrazepam [Rohypnol])	Drowsiness, disinhibition, ataxia, slurred speech, mental confusion, respiratory depression, progressive central nervous system depression, hypotension
Cholinergic (Examples: diazinon, Orthene, parathion, nerve gas)	Increased salivation, lacrimation (tearing), excess defecation or urination, nausea or vomiting, airway compromise, seizures, coma
Anticholinergic (Examples: atropine, scopolamine, antihistamines, antipsychotics, Jimsonweed)	Tachycardia, hyperthermia, dry skin and mucous membranes, dilated pupils, blurred vision, sedation, agitation, seizures, coma, or delirium

TABLE 23-2 Common Signs and Symptoms of Poisoning

Sign or Symptom	Type	Possible Causative Agents
Odor	Bitter almonds	Cyanide
	Garlic	Arsenic, organophosphates, phosphorus
	Acetone	Methyl alcohol, isopropyl alcohol, aspirin, acetone
	Wintergreen	Methyl salicylate
	Pears	Chloral hydrate
	Violets	Turpentine
	Camphor	Camphor
	Alcohol	Alcohol
Pupils	Constricted	Opioids, organophosphates, propoxyphene (Darvon)
	Dilated	Barbiturates, atropine, amphetamine, glutethimide (Doriden), LSD, cyanide, CO
Mouth	Salivation	Organophosphates, arsenic, strychnine, mercury, salicylates
	Dry mouth	Atropine (belladonna), amphetamines, diphenhydramine (Benadryl), opioids
	Burns in mouth	Formaldehyde, iodine, lye, toxic plants, phenols, phosphorus, pine oil, silver nitrate, acids
Skin	Pruritus	Jimsonweed, belladonna, boric acid
	Dry, hot skin	Atropine (in belladonna), botulism, nutmeg
	Sweating	Organophosphates, arsenic, aspirin, amphetamines, barbiturates, mushrooms, naphthalene
Respiratory	Depressed respirations	Opioids, alcohol, propoxyphene, CO, barbiturates
	Increased respirations	Aspirin, amphetamines, boric acid, cyanide, kerosene, methyl alcohol, nicotine
	Pulmonary edema	Organophosphates, petroleum products, opioids, CO
Cardiovascular	Tachycardia	Alcohol, amphetamines, arsenic, atropine, aspirin, cocaine, some anti-asthma drugs
	Bradycardia	Digitalis, gasoline, nicotine, mushrooms, opioids, cyanide, mistletoe, rhododendron
	Hypertension	Amphetamines, lead, nicotine, antiasthma drugs
	Hypotension	Barbiturates, opioids, tranquilizers, house plants, mistletoe, nitroglycerin, antifreeze
Central nervous system	Seizures	Amphetamines, camphor, cocaine, strychnine, arsenic, carbon monoxide, petroleum products, scorpion sting
	Coma	All depressant drugs (such as opioids, barbiturates, tranquilizers, alcohol), CO, cyanide
	Hallucinations	Atropine, LSD, mushrooms, organic solvents, phencyclidine, nutmeg
	Headache	CO, alcohol, disulfiram (Antabuse)
	Tremors	Organophosphates, CO, amphetamine, tranquilizers, poisonous marine animals
	Weakness or paralysis	Organophosphates, botulism, eel, hemlock, puffer fish, pine oil, rhododendron
Gastrointestinal	Cramps, nausea, vomiting, and/or diarrhea	Many, if not most, ingested poisons

Abbreviations: CO, carbon monoxide; LSD, lysergic acid diethylamide

evolution of the substances themselves. Substance abuse can be broadly defined as the self-administration of licit or illicit substances in a manner not in accordance with approved medical or social practice. Part of that definition is cultural—and there is great variation in what is considered substance abuse.

Any given society's definition of abuse may have little relation to the potential harm from the abused substance. For example, US culture places no restrictions on the long-term and compulsive use of tobacco, even though this substance is a major contributor to cardiovascular and respiratory disease. By comparison, use of marijuana may be punishable by fines or imprisonment, although some states have legalized the use of small amounts for personal recreational purposes and/or the use of medical marijuana to treat pain, nausea, and some other symptoms.

The following list defines some basic terms and concepts related to substance abuse:

- **Drug abuse.** Any use of drugs that causes physical, psychological, economic, legal, or social harm to the user or to others affected by the drug user's behavior.
- **Habituation.** Psychological dependence on a drug or drugs; may also include physiologic tolerance when a drug is used repeatedly.
- **Physical dependence.** A physiologic state of adaptation to a drug, usually characterized by tolerance to the drug's effects and a withdrawal syndrome if the drug is stopped, especially if it is stopped abruptly.
- **Psychological dependence.** The emotional state of craving a drug to maintain a feeling of well-being.
- **Tolerance.** Physiologic adaptation to the effects of a drug such that increasingly larger doses of the drug are required to achieve the same effect.
- **Withdrawal syndrome.** A predictable set of signs and symptoms, usually involving altered CNS activity, that occurs after the abrupt cessation of a drug or after rapidly decreasing the usual dosage of a drug.
- **Drug addiction.** A chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user, who continues to use the substance despite the harm.
- **Antagonist.** Something that counteracts the action of something else. In relation to drugs, a drug that is an antagonist has an affinity for a cell receptor; by binding to the receptor, the antagonist prevents the cell from responding.
- **Potentiation.** Enhancement of the effect of one drug by another drug.

YOU are the Provider

Part 2

The police officers are able to successfully subdue the patient using minimal force and place him in handcuffs. The officers then motion you over. Your initial impression reveals a severely agitated, thin-appearing man who is screaming incoherently and who has what appears to be severe abrasions on each forearm. The patient has a patent airway as evidenced by his screaming, and the bleeding appears to be superficial. You immediately place a blanket over the patient. As you question the patient, he keeps screaming, "Don't let them get me! I'm burning! God help me!" A family member who has arrived at the scene approaches you.

Recording Time: 1 Minute

Appearance	Anxious, agitated
Level of consciousness	Alert, but does not appear to be oriented to person, place, time, or event
Airway	Patent
Breathing	Rapid, panting
Circulation	Strong radial pulses; skin warm and dry

3. Does this patient's presentation warrant transport via EMS, or should he be transported via law enforcement?
4. Should you request paramedic backup for this patient?

- **Synergism.** The action of two substances such as drugs, in which the total effect is greater than the sum of the independent effects of the two substances (that is, $2 + 2 = 5$).

Drug abuse is not limited to members of the younger generation or to any particular stratum of society. It occurs in all age groups and at all social levels. However, adolescents are susceptible to experimentation with drugs of abuse because of curiosity and peer pressure.

Patient Assessment

Generally, patients with toxicologic emergencies are considered medical patients, although toxicologic emergencies may also lead to trauma. The general assessment approach is the same for all patients: scene size-up, primary survey, history taking, secondary assessment, and reassessment.

Documentation and Communication

While at the scene, take thorough (and legible) notes about the nature of the poisoning. You can then quickly state the type and amount of substance and the time and route of exposure in your radio, verbal, and written reports. Clear notes that can be handed over on arrival will be appreciated by busy hospital staff.

Scene Size-up

When you have a situation that involves a toxicologic emergency, a well-trained dispatcher is of great value. Dispatchers with an appropriate set of protocols and excellent interrogation skills can obtain important information pertaining to a poisoning call that will help you anticipate the proper protection needed to ensure your safety. If this information is not obtained before your arrival, you must take the time to thoroughly assess the scene to ensure your safety. Determine the nature of the illness and any mechanism of injury, as well as the number of patients involved, the need for additional resources, and the need for spinal immobilization.

Because of the risk of possible cross-contamination by poisons that can be inhaled, absorbed, ingested, and injected, you must take appropriate standard precautions. Wear the appropriate personal protective equipment necessary to avoid being contaminated.

Patients who have taken an overdose may be extremely dangerous. If necessary, call for law enforcement backup.

As you approach the scene, look for clues that might indicate the substance or poison involved:

- Are there medication bottles lying around the patient and the scene? If so, is there medication missing that might indicate an overdose?
- Are there alcoholic beverage containers present?
- Are there syringes or other drug paraphernalia on the scene?
- Is there an unpleasant or odd odor in the room? If so, is the scene safe? An odor could also be a clue to an inhaled poison.
- Is there a suspicious odor or drug paraphernalia present that may indicate the presence of a clandestine drug laboratory? Drug laboratories can be very volatile, so ensure scene safety before trying to access the patient (**FIGURE 23-3**).

Keep a constant observant eye on the surroundings, and keep an open mind when questioning the patient or bystanders to avoid coming to mistaken conclusions.

Safety

Scene safety is your primary concern when you are called to an inhalation incident. Whenever you encounter more than one patient but find no evidence of the mechanism of injury, be suspicious. Toxic fumes may be odorless and colorless, and they can affect you as well as the patients. Be suspicious of toxic fumes when encountering patients with changes in level of consciousness, especially at an industrial site or enclosed space.

Primary Survey

The primary survey of a drug-overdosed or poisoned patient begins with your general impression. That impression can be as simple as “a young adult man snoring in a public bathroom stall.” Conversely, do not be fooled into thinking that a patient who is responsive, alert, and oriented is in stable condition and has no apparent life threats. In some cases, patients may have a harmful or even lethal amount of poison in their system that has just not had enough time to produce a systemic reaction.

Begin your assessment by identifying any life threats (assess airway, breathing, circulation, disability, and exposure [ABCDEs]). The primary survey may also identify the mechanism of injury or nature of illness, suggest the need for additional units, and set the priority and tone of the call. A primary survey that reveals a patient with signs of distress or altered mental status gives you early confirmation that the poisonous substance is causing a systemic reaction.

Manage life threats quickly. Ensure the patient has an open airway and adequate ventilation. Do not hesitate to begin oxygen therapy for the patient. If the patient is unresponsive to painful stimuli, then consider inserting an airway adjunct to ensure the airway remains open. Have suction available; patients who have been poisoned are susceptible to vomiting. You may also have to assist a patient's ventilations with a bag-mask device, because some substances act as depressants on the body's systems. As you assess and manage the patient's airway and breathing, consider the potential for spinal injury. Spinal precautions in an unresponsive patient must begin when the airway is first opened

and be continued if positive-pressure ventilations are needed.

Use diagnostic tools such as the pulse oximeter, but remember, if the patient has been exposed to some chemicals, such as CO, cyanides, and nitrites, the reading will be inaccurate. CO has a 200 to 250 times greater affinity for hemoglobin than does oxygen, which causes oxygen molecules to be displaced from hemoglobin. Thus, the reading on the pulse oximeter will be at or near 100% in a patient with CO poisoning because the hemoglobin is completely saturated—though it is saturated with CO molecules rather than oxygen. Always treat the patient, not the diagnostic tool; never withhold oxygen based on a pulse oximeter reading if you suspect CO poisoning or if it is even a remote possibility! Treatment for CO poisoning consists of high-flow oxygen and transport of the patient to the closest, most appropriate facility.

Once you have assessed the patient's airway and breathing and performed the appropriate interventions, assess the patient's circulatory status. Patients' circulatory status will vary depending on the substance involved in a poisoning. Assess the pulse and skin condition. Remember that some poisons are stimulants, and others are depressants. Stimulant exposure may result in restlessness, agitation, incessant talking, insomnia, anorexia, dilated pupils, tachycardia, tachypnea, hypertension or hypotension, paranoia, seizures, and/or cardiac arrest, whereas depressant exposure generally presents with respiratory depression, bradycardia, drowsiness, and possible coma. Some poisons cause vasoconstriction, whereas others trigger vasodilation. Although bleeding may not be obvious, alterations in consciousness may have contributed to trauma and bleeding.

Also, assess for disability, and expose the patient to identify any additional conditions.

Patients with obvious alterations in the ABCs and patients whom you assess as having a poor general impression should be considered for immediate transport. A delay on the scene to further assess and treat such patients is rarely indicated.

Some industrial settings may have specific decontamination stations and antidotes for specific toxic substances present at the site. Some of the time, decontamination and antidote administration will have been initiated by the industrial response team before your arrival and should not delay rapid

transport. Your own decontamination of the patient may sometimes be needed before transport, depending on the poison involved. For example, this action is necessary if a patient continues to off-gas or if your crew has the potential to become exposed in the confined space of the ambulance during transit. Decontamination is especially important when transporting exposed patients in a helicopter.

History Taking

After completing the primary survey, begin obtaining the history. Many poisoning and overdose cases involve patients with medical conditions, so you will need to elaborate on their chief complaint using the OPQRST-I mnemonic (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions). Obtain the patient's medical history. In many situations, this step can be performed in the ambulance en route to the hospital. If the patient is responsive and can answer questions, begin with an evaluation of the exposure and the SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history. If the patient is not responsive, attempt to obtain the history from other sources, such as friends or family members. Medical identification jewelry and cards in wallets may also provide information about the patient's medical history.

In toxicologic emergencies, the SAMPLE history guides your focus as you continue to assess the patient's complaints. The physical exam helps to determine the visible signs of a reaction to the toxin. Vital signs may indicate any physiologic response to the exposure as well as give you an indication of the urgency. These three assessments are important in that they give you direction in determining the best interventions for the patient. To choose the appropriate course of action in a toxicologic emergency, obtain at least the following specific information:

- **What is the agent?** If you know the substance involved, you will be better able to access the appropriate resource, such as the poison center, to determine lethal doses, time before harmful effects begin, effects of the substance at toxic levels, and appropriate interventions.

- **When was the poison ingested, injected, absorbed, or inhaled?** This information will let you know if and when any harmful effects will begin. It will also tell the emergency physician which harmful effects can be reversed and which cannot because of the length of time that the patient has been exposed to the substance. The decision to flush out (lavage) the stomach is strongly influenced by the amount of time that has elapsed since the exposure. Also, acute-onset events often indicate a more serious patient scenario; if, for example, the patient is having crushing chest pain, then knowing that the patient smoked crack cocaine 15 minutes ago will offer insight into the urgency of the situation.
- **How much was taken, injected, absorbed, or inhaled?** Based on this information, the poison center will be able to determine whether the patient has received a harmful or lethal dose. For example, if the patient says that she took four tabs of Ecstasy, that amount is four times the single dose. In toxicologic emergencies, there is almost always a direct correlation between dose and toxic effects.
- **What else was taken?** Most intentional self-poisonings (suicide attempts) or illicit drug overdoses involve polydrug ingestions, with alcohol often being one of the drugs taken.^{4,5} The patient may also have tried to take something to counteract the effect of the poison. This information can be invaluable to the ED staff when deciding which tests to order.
- **Over what period did the patient take the substance?** All at once or over minutes or hours?
- **Has the patient or a bystander performed any intervention?** Has the intervention helped? The patient's or bystander's intervention may cause more complications. The emergency physician will also need to know this information to be able to adjust subsequent interventions accordingly.
- **Has the patient vomited or aspirated?** If so, how soon after the ingestion or exposure? How much?
- **How much does the patient weigh?** If activated charcoal is indicated, you will need to determine the dose based on the patient's

FIGURE 23-4 Take any bottles, containers, and their remaining contents to the emergency department.

© John Moore/Staff/Getty Images News/Getty Images.

weight. The antidote or neutralizing agent given by the emergency physician may be based on the patient's weight as well.

- **Why was the substance taken?** Although you may not get a reliable answer from someone abusing illicit drugs, this is still a question worth asking. Do not assume every patient is trying to get high. Drug use could be a coping mechanism for a person who is being abused, or it could be a suicide attempt. Put the reason in quotation marks on your patient care report.

If the patient has overdosed on a prescription drug, take the pill bottle and the remaining pills to the ED with the patient (**FIGURE 23-4**). If the substance was a commercial product, take the container and its remaining contents to the ED. If the patient ingested a plant, find out which part (roots, leaves, stem, flower, or fruit) and take a sample of the plant to the ED for identification. If the patient vomits, save a sample of the vomitus in a clean, closed container.

Secondary Assessment

Your physical examination of a patient with a toxicologic emergency should focus on the area of the body involved with the poisoning or the route of exposure. For example, if the patient has ingested a poison, inspect the mouth for indications of poisoning. Are there burns from caustic chemicals? Are there plant or pill fragments? If the person's

skin came in contact with a poison, is there a rash or burns? How large is the involved area? If a respiratory exposure occurred, auscultate the lungs. Is there good air movement in and out of the lungs? Do you hear any wheezing or crackles? The specific focus of your physical exam is largely based on the route of exposure and the specific drug or chemical that was involved. Take the time to become knowledgeable about the effects of general classes of drugs and chemicals so you will be familiar with how to assess and treat patients who are exposed to specific and common poisons.

Managing life threats during the primary survey is the priority assessment and treatment goal. Once the life threats have been addressed, conducting a thorough physical exam will often provide additional information on the patient's toxicologic exposure. A general review of all body systems may help to identify systemic problems. This review should be performed, at a minimum, on patients with extensive chemical burns or other significant trauma and on patients who are unresponsive. This should be done en route, so as not to delay transport.

A complete set of baseline vital signs is an important tool for you to use to determine how the patient is doing. Many poisons produce no outward indications of the seriousness of the exposure. Alterations in the level of consciousness, pulse, respirations, blood pressure, and skin are more sensitive indicators that something serious is wrong. Be aware that exposure to CO may produce false pulse oximetry readings. Monitor end-tidal carbon dioxide (ETCO₂) if CO exposure is suspected.

Special Populations

Geriatric patients may have become confused about their drug regimen, resulting in an accidental overdose or poisoning. They may have forgotten that a medication was taken earlier, and repeat the dose one or more times. The patient could also have forgotten or misunderstood the doctor's instructions to stop a medication and may have taken both the current and older drugs, resulting in increased effects or unwanted drug interactions. A geriatric patient may also intentionally overdose in a suicide attempt.

Assessment Pearls

- Exposure to various toxins, especially those inhaled, injected, or chewed (as with plant leaves), can result in rapid airway changes. Reassess frequently!
- Where did you find the patient? A farmer working in a field should alert you to possible organophosphate involvement, and a patient in an enclosed space with a kerosene heater should trigger thoughts of carbon monoxide.
- If everyone in the same area has the same symptoms, there is an environmental issue. Think scene safety! Wait for those properly trained and attired to enter and bring the patient or patients to you.
- It is best to use the appropriate decontamination method. However, a good rule of thumb if you cannot identify the actual toxin is to flush liquids with copious amounts of water and brush off as much of a powder as possible *before* flushing with water.
- Take *all* items implicated in the exposure with you to the hospital: plants, bottles, even unmarked containers! Such items will help with early recognition of the toxin and rapid treatment. If there is a concern about the safety of the container, take a picture instead.
- Check pupils! Pinpoint pupils may be the result of opioids or organophosphates. Jimsonweed and toxic mushrooms can cause dilated pupils.
- Use ETCO₂ for suspected CO exposure. Pulse oximeters cannot detect the difference between oxygen and CO.

Reassessment

The condition of patients exposed to poisons may change suddenly and without warning. You should continually reassess the adequacy of the patient's ABCDEs. Record the vital signs again, and compare them with the baseline set obtained earlier in your assessment. Evaluate the effectiveness of any interventions you have provided. If your assessment has obtained specific, pertinent information about the poisonous substance, you may be able to anticipate changes in the patient's condition. If the patient has consumed a harmful or lethal dose of a poisonous substance, you must reassess the patient's vital signs every 5 minutes, or more often if necessary. If the patient is in stable condition and there are no life threats, reassess your patient every 15 minutes.

If the poison or the level of exposure is unknown, then it is mandatory for you to perform a careful and frequent reassessment.

The treatment you provide for poisoned patients depends a great deal on the substance to which they were exposed, the route of exposure, and other signs and symptoms uncovered in your assessment. Supporting these patients' ABCs is your most important task. Some poisons can be easily diluted or patients decontaminated before transport or en route to the hospital: dilute airborne exposures with oxygen, remove contact exposures with copious amounts of water unless contraindicated, and consider administering activated charcoal for ingested poisons. Remember, these patients may vomit at any time, so continuously monitor the airway. Contact medical control or a poison center to discuss treatment options for specific poisonings.

Once you have completed your primary survey, history taking, and secondary assessment, contact medical control for advice on necessary interventions. Report to the hospital as much information as you have about the poison or chemical to which the patient was exposed. If a safety data sheet is immediately available in a work setting, take it with you to the hospital. If this document is not immediately available, ask the company to send it (eg, via email or fax) to the receiving hospital while you are en route. This information will help hospital providers identify and quickly make available specific interventions and potential antidotes.

Words of Wisdom

Have someone count the medications left in the prescription bottle and compare to the date filled to figure out the maximum quantity the patient might have taken.

Emergency Medical Care

First, ensure scene safety by taking standard precautions and performing external decontamination, if indicated after consulting poison control and/or medical control. Remove tablets or fragments from the patient's mouth, and wash or brush poison from the patient's skin. Treatment focuses on support: assessing and maintaining the patient's ABCs and monitoring the patient's breathing. Administer

oxygen to the patient as needed, and assist ventilations if necessary. If the patient has signs and symptoms of shock, provide treatment according to your local protocol.

In some cases, you may administer activated charcoal to patients who have ingested certain poisons, if approved by medical control or local protocol. Activated charcoal is not indicated for patients who have ingested an acid, an alkali, or a petroleum product; who have a decreased level of consciousness and cannot protect their airways; or who are unable to swallow.

Activated charcoal adsorbs, or sticks to, many commonly ingested poisons, preventing the toxin from being absorbed into the body by the stomach or intestines. If your local protocol permits, you will likely carry plastic bottles of premixed suspension, each containing up to 50 g of activated charcoal. Some common trade names for the suspension form are Insta-Char, Actidose, and Liqui-Char. The usual dose is 1 g of activated charcoal per kilogram of body weight, which translates into 50 to 100 g for adults, 25 to 50 g for children, and 10 to 25 g for infants.

As mentioned earlier, administration of activated charcoal is associated with severe risk of aspiration. Never administer activated charcoal to patients who are not alert or are unable (or may become unable) to protect their own airway. Always check with medical control and/or poison control prior to administering.

Once medical control has given orders to administer activated charcoal, shake the bottle vigorously to mix the suspension. This medication looks like mud, so it is best to cover the outside of the container so the fluid is not visible and ask the patient to drink it with a straw. Activated charcoal is an inky, messy fluid, so you may have to do some coaxing to get the patient to drink it; try to give it in a covered cup with a straw. Remember, you should never force this (or any other) liquid into a patient's mouth. If the patient takes a long time to drink the mixture, you will have to shake the container frequently to keep the medication mixed. Once the patient has finished, discard the container from which the charcoal was administered. Ensure you record the time when you administered the activated charcoal.

A major side effect of ingesting activated charcoal is black stools. Patients who have ingested a poison that causes nausea may vomit after taking

activated charcoal, and the dose will have to be repeated. As you reassess the patient, be prepared for vomiting, nausea, and possible airway problems.

Pathophysiology, Assessment, and Management of Specific Poisons

Alcohol

Alcohol is the most widely abused drug in the United States and around the world. In the 2018 National Survey on Drug Use and Health, 86% of US adults reported drinking alcohol at some point in their lifetime; more than 14 million US adults had alcoholism.⁶ **Alcoholism**, a state of physical and psychological addiction, is the fourth leading cause of death in the United States, with an estimated 95,000 alcohol-related deaths annually.⁶ Worldwide, nearly 6% of all deaths (more than 3 million deaths in 2012) are attributable to alcohol consumption.⁶ In addition, people with alcoholism tend to have chronic malnutrition and fall frequently, increasing the likelihood of head injury or other trauma.

Alcohol is a powerful CNS depressant. It is both a sedative (it decreases activity and excitement) and a hypnotic (it induces sleep). In general, alcohol dulls the sense of awareness, slows reflexes, and slows reaction time. It may also cause aggressive and inappropriate behavior and lack of coordination. However, a person who appears intoxicated may have other medical conditions as well. When you are treating a patient, look for signs of head trauma, toxic reactions, or uncontrolled diabetes. Severe acute alcohol ingestion may cause hypoglycemia, which may contribute to the symptoms. At the least, you should assume all intoxicated patients are experiencing other possible medical issues and require a thorough exam by a physician.

Severe alcohol intoxication is a form of poisoning and has the same lethal potential as poisoning with any other CNS depressant. The most immediate danger to an acutely intoxicated person is death from respiratory depression and/or aspiration of vomitus or stomach contents secondary to a suppressed gag reflex.

Physical dependence on alcohol results from the regular consumption of large quantities. This dependence becomes apparent when a person abruptly stops consuming alcohol and withdrawal

symptoms result. The severity of the withdrawal can vary according to the length and intensity of the alcoholic habit. Minor withdrawal is characterized by restlessness, anxiousness, sleeping problems, agitation, and tremors. Major withdrawal symptoms include increased blood pressure, vomiting, and hallucinations. **Delirium tremens (DTs)**, or alcohol withdrawal delirium, results in tremors and restlessness, weakness, fever, diaphoresis, disorientation, hallucinations, confusion, hypotension, seizures, and possibly death.

Because of the toxic effects of alcohol, a person with alcoholism is considerably more susceptible than a sober person to many serious illnesses and injuries (**TABLE 23-3**). The most common long-term effect is liver damage; up to 35% of heavy drinkers will develop alcoholic hepatitis, and 10% to 20% of alcoholics will develop cirrhosis.⁷ Other long-term effects of alcoholism include an increased incidence of pancreatitis, development of erosive gastritis, and an increased risk for breast and colorectal

cancer. The long-term abuse of alcohol leads to atrophy of the cerebrum, possibly resulting in permanently reduced mental function.

If an intoxicated patient is unresponsive, treat the person as you would any unresponsive patient. As always, first establish and maintain the airway. If the patient has an intact gag reflex, place the patient in left lateral recumbent position with suction ready; the patient may vomit forcefully and the vomit may be bloody because large amounts of alcohol irritate the stomach. If there is no gag reflex, place an appropriate airway adjunct and ventilate the patient with a bag-mask device or consider calling for paramedic backup for intubation and cardiac monitoring. In addition, administer supplemental oxygen to maintain an SpO₂ of greater than 94% and assist ventilation as needed. Consider the use of EtCO₂ if available. Establish vascular access. Assess the patient's blood glucose level, treating hypoglycemia if it is found. Finally, transport the patient to an appropriate facility.

TABLE 23-3 Medical Conditions to Which People With Alcoholism Are Particularly Susceptible

Condition	Contributing Factors
Subdural hematoma	Frequent falls; impaired clotting mechanisms; brain atrophy allows for significant movement during impact
Gastrointestinal bleeding	Irritated stomach lining, leading to gastritis; impaired clotting mechanisms; cirrhosis (excess scar tissue) of the liver, leading to engorgement of esophageal veins (esophageal varices)
Pancreatitis	Secretion of enzymes, causing inflammation
Hypoglycemia	Damaged liver; impairs gluconeogenesis
Pneumonia	Aspiration of vomitus occurring during intoxication and coma; suppressed immune system by alcohol
Burns	Risky behaviors during intoxication; decreased pain sensitivity during intoxication
Hypothermia	Insensitivity to extreme temperatures while intoxicated; falling asleep outside in the cold; impaired thermoregulation
Seizures	Effects of alcohol withdrawal; neurotransmitter or electrolyte imbalance
Dysrhythmias (atrial fibrillation or ventricular tachycardia)	Toxic effects of alcohol on the heart; hypertension; electrolyte imbalance
Cancer	Damaged liver from heavy alcohol use; may cause alterations in normal cellular pathways
Esophageal varices	Obstructed blood flow to the liver, causing blood to back up into smaller, more fragile blood vessels in the esophagus

Suspect internal bleeding if the patient appears to be in shock (hypoperfusion). Blood might not clot effectively in a patient who has a prolonged history of alcohol abuse.

A person who has been drinking heavily for an extended period and suddenly stops drinking may have a variety of withdrawal phenomena. Seizures usually occur within 12 to 48 hours of the last drink. Use the same care plan described for alcohol intoxication, and call for paramedic backup to administer benzodiazepines for seizure control.

The treatment for a patient in DTs is aimed at protecting the person from injury and supporting the cardiovascular system. The often-terrifying hallucinations associated with DTs typically make for an agitated, often combative patient. Try to keep the patient calm. In addition, administer oxygen by nasal cannula and establish vascular access. Manage hypotension with an infusion of normal saline, and, during the reassessment, reassess breath sounds. Maintain an ongoing dialogue with the patient throughout transport to help orient and reassure the patient.

Opioids

An **opioid** is a drug that acts as a central nervous system depressant and produces insensibility or stupor. An opioid can be a natural product derived from the opium or poppy plant (referred to more specifically as an **opiate**) or a synthetic product designed to produce similar effects. Abuse of opioids remains one of the most common causes of overdose deaths reported to poison centers, and the majority (two-thirds) of deaths from drug overdoses in the United States involve an opioid.⁸ Since 1999, the rate of overdose deaths involving opioids, including prescription opioid pain relievers and heroin, has increased by almost six times, leading to a veritable opioid epidemic today.⁸ In 2015, more than 33,000 deaths from drug overdoses in the United States involved an opioid; in 2018, that number had increased to 47,000.^{8,9}

Words of Wisdom

Narcotic originally referred to a substance that dulled the senses and relieved pain. In everyday speech, the term often refers to all illegal drugs, but technically, it refers only to opioids. To avoid confusion, opioid is the preferred term in the medical community.

Opioids include morphine, codeine, heroin, fentanyl, oxycodone, meperidine, propoxyphene, and dextromethorphan. Although these drugs share certain commonalities, they exhibit highly diverse effects and vary widely in their potency. Opioids are used primarily in clinical medicine for analgesia, whereas the illicit drug heroin is abused for the unique euphoria it produces. Some of these drugs, such as fentanyl and its derivatives (eg, carfentanil), are so potent that they can present a danger to you and other providers if you are exposed while caring for a patient.

Opioids produce their major effects on the CNS by binding with receptor sites in the brain and other tissues. These agents are readily absorbed from the gastrointestinal tract but can also be absorbed from the nasal mucosa (when snorted) or from the lungs (when smoked). When taken orally, the effects of opioid drugs are lessened compared with their effects when given parenterally. When heroin passes through the liver, it is metabolized into acetyl morphine, which continues to exert opioid effects that may outlast the effects of naloxone (an opioid antagonist discussed next). An AEMT who does not understand this concept can be fooled into thinking that a dose of naloxone has permanently reversed the effects of the heroin, only to have the patient lapse into unresponsiveness 15 or 20 minutes later.

Morphine is a commonly used analgesic in the prehospital setting and is a potent vasodilator. The half-life of morphine is roughly 2 to 3 hours, but it typically takes longer to metabolize in older adults.

The classic presentation of opioid use features euphoria, hypotension, respiratory depression, and pinpoint pupils. Depending on the particular agent, nausea, vomiting, and constipation may occur as well. Allergic phenomena may also occur with opioid use, albeit rarely. With increased doses, coma, seizures (usually secondary to hypoxia), and cardiac arrest (usually secondary to respiratory arrest) are common.

Morphine and heroin produce an impressive dreamlike state. Shortly after injecting heroin, a user may appear to pass out. However, the user is typically quite lucid and remains aware of what is being done or said.

Naloxone (Narcan) is an antidote that reverses the effects of opioid overdose. This medication can be administered via an IV line, intramuscularly (IM), or intranasally. Ideally, naloxone is administered via IV access. However, in many instances,

Safety

A relatively new safety hazard has surfaced in the form of synthetic opioids that are analogs of fentanyl. They have been associated with an epidemic of opioid-related overdose deaths.¹⁰ One such drug, *carfentanil*, is 10,000 times more powerful than morphine. Fentanyl is similar to heroin and morphine, but is 50 to 100 times more potent than either.¹¹ These drugs are also being mixed with heroin to make them even more potent.

Carfentanil was designed for use by veterinarians to treat large animals such as horses, elephants, and the like. It acts quickly to depress the respiratory centers and CNS. Very small amounts can be detrimental to humans and possibly fatal. Although carfentanil is supplied in patches, powder, tablets, and spray, routes of exposure for first responders typically include absorption through the skin and inhalation via the respiratory tract. Law enforcement, firefighters, EMS, and even police dogs are at risk of exposure.¹²

Although naloxone will work to counteract overdoses, it may take substantial amounts to make a difference. Personal protective equipment should include mask, gloves, and eye protection. Do not touch any substance that looks suspicious. Along with the risk of exposure to the substances, responders also face the potential for violent attacks from the patient when naloxone is used to reverse the effects of the drugs. Be prepared and call early for paramedic or law enforcement assistance.

IV access is difficult to obtain in the chronic user of illicit IV drugs such as heroin. These patients have venous scarring, called track marks, from repeated use of needles on peripheral veins. Therefore, the intranasal route is becoming a preferred alternative route for administering naloxone. It is safer than administering an IM injection because a needle is not required to administer the medication. The dosage of naloxone is 0.4 to 2 mg.

Some EMS systems allow AEMTs to administer naloxone by the intranasal route, in which the antidote is atomized through the nares into the nasal mucosa. Be aware that the administration of naloxone may precipitate withdrawal symptoms resulting in violent behavior and/or seizure activity. Also, acute opioid reversal may lead to vomiting and aspiration.¹³ This medication should only be used when the patient has agonal respirations or apnea. Place an oropharyngeal (oral) or nasopharyngeal (nasal) airway and ventilate the patient using a bag-mask device prior to administering naloxone.

Words of Wisdom

In some areas, laypeople are permitted to administer naloxone. Be aware that it may have been administered prior to your arrival and the patient may be combative. Question bystanders about what occurred, how naloxone was administered, when it was administered, and the patient's response to the medication.

Provide adequate ventilation while administering naloxone to decrease the risk of permanent brain damage related to hypoxia.

Closely monitor the patient. As the patient's level of consciousness rises, the patient will no longer tolerate the oropharyngeal airway, so you will have to remove it to prevent aspiration.

If a patient goes into cardiac arrest, follow the algorithm shown in **FIGURE 23-5**, including administering naloxone if it is available. However, providing bag-mask ventilations is a critical treatment for these patients as well. Whether or not naloxone is available, provide ventilations and rapid transport.

If the patient does not respond to naloxone, it is possible that the person has a “mixed-bag overdose”; that is, the patient may have taken multiple drugs, some of which are not opioids, and will not respond to naloxone or may need a subsequent dose.¹⁴ Alternatively, the lack of responsiveness may be from another source altogether, such as a head injury. In such a scenario, insert an advanced airway (eg, a Combitube, King airway, or laryngeal mask airway), provide other care as needed, and transport the patient to an appropriate facility. Call early for paramedic backup if needed.

Words of Wisdom

Remember the importance of performing a rapid full-body scan of patients who have overdosed on opioids. People may use multiple routes of administration when abusing opioids, including transdermal patches. Missing a fentanyl patch that was covered by clothing could lead to the patient lapsing back into respiratory arrest. Look in discreet areas such as between the cheeks of the buttocks, the inner thighs, and other areas that are not readily visible when clothing is removed. If you have not found and removed the patch, then you may not be successful in treating the life-threatening overdose.

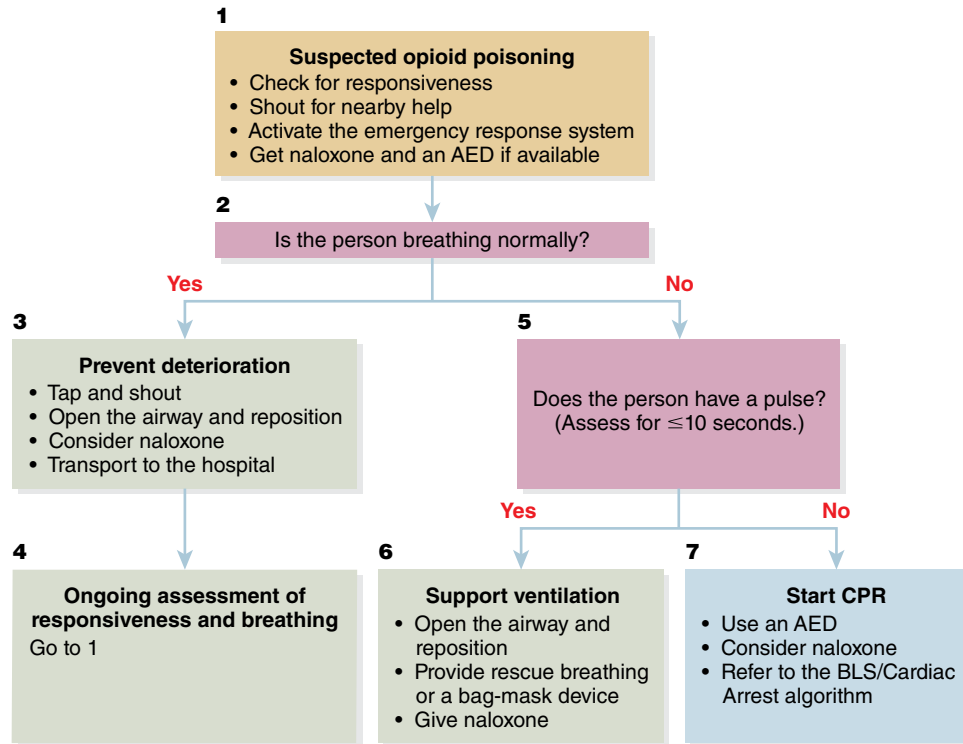

FIGURE 23-5 The American Heart Association's algorithm for life-threatening opioid overdose. Abbreviations: AED, automated external defibrillator; BLS, basic life support

Reprinted with permission *Circulation*.2020;142:S366-S468 ©2020 American Heart Association, Inc.

When caring for a patient who has overdosed on opioids, it is important to remember that the patient may have other underlying chronic illnesses or conditions, such as hepatitis, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), malnutrition, or sepsis. Medications taken for any of these conditions may interact with the opioid, creating myriad signs and symptoms.

Older patients often take multiple medications for pain due to arthritis, degenerative diseases, and other conditions. For those patients who have chronic pain and regularly take large doses of opioids, dependency may become a major problem. Using an opioid antagonist in such a patient may cause withdrawal and result in seizures or other problems. Closely monitor these patients and provide prompt transport to the closest appropriate facility.

When you prepare your patient care report, ensure you document whether the ingestion was intentional or accidental, how much was taken, and what was taken. Also document whether the patient has vomited since ingestion. Take any pills or

bottles to the hospital with the patient. Report all findings to receiving personnel at the ED, and also report any illicit substances to law enforcement.

Stimulants

Few drugs compare with **stimulants** in potential for abuse—particularly cocaine, **amphetamines**, and **methamphetamine**. As with opioids, a first-time user may become an addict to one of these substances within just a few days.¹⁵ If the person decides to quit using the stimulant, it is unlikely that abstinence will be successful. In 2018, nearly 1 million people in the United States had a cocaine use disorder, more than 1.1 million had a methamphetamine use disorder, and hundreds of thousands more had a stimulant use disorder relating to other drugs, such as misused prescription medications.¹⁶

Depending on the formulation, stimulant drugs may be taken orally, smoked, or via IV injection. The clinical presentation of the stimulant abuser includes excitement, delirium, tachycardia, hypertension or hypotension with a fast pulse rate, and dilated pupils. As toxic levels are reached, the

patient may experience psychosis, hyperpyrexia, tremors, seizures, and cardiac arrest.

Cocaine is a naturally occurring alkaloid that is extracted from the *Erythroxylon coca* plant leaves found in South America. Once processed into cocaine hydrochloride, the active ingredient in the leaves becomes 100% pure, dramatically increasing its toxic potential. Cocaine is sold under many street names (eg, blow, Coke, stash, nose candy, snow, dust). It is a local anesthetic and a CNS stimulant that can create euphoria that features enhanced alertness and a tremendous sense of well-being. Collectively, these effects make cocaine one of the most, if not the most, psychologically addictive drug available.

Cocaine is quickly absorbed across all mucosal membranes, allowing it to be applied topically, swallowed, snorted, or via IV injection. Also, this drug may be mixed with two inexpensive ingredients, baking soda and water. Once mixed together into a pastelike slurry and cooked or baked, the end result is smokable cocaine (known as crack).

When cocaine is snorted nasally, the effects are felt within 1 to 2 minutes, and peak effects occur in 20 to 30 minutes. When it is smoked, the onset of effects is much more rapid (8 to 10 seconds) and the high is more intense, though the effects do not last as long, leading to binge redosing.

When the effects of cocaine wear off, the user experiences a “crash,” characterized by depression, irritability, sleeplessness, and exhaustion. Depending on the amount and length of cocaine use, the person may experience a cascade of adverse effects collectively referred to as *cocaine washout syndrome*. This syndrome presents as a hypoactive state related to a lack of synaptic neurotransmitters. To avoid this crash, the user will often seek more cocaine. Adding to the problem, a person addicted to cocaine who is trying to escape the unpleasant effects of a crash often takes a sedative (such as diazepam [Valium], alcohol, or heroin). Thus, a chronic cocaine user may practice polypharmacy and be dependent on more substances than cocaine, increasing the likelihood that the person will need EMS care, possibly overdosing on amphetamines, barbiturates, or both.

Amphetamines are structurally similar to the derivatives of phenylethylamine and include methamphetamine (crank or ice), methylenedioxymphetamine (MDA, Adam), and methylenedioxymphetamine (MDMA, Eve, Ecstasy).

FIGURE 23-6 Nasal decongestants and diet pills generally fall into the category of amphetamines.

© Jones & Bartlett Learning. Photographed by Kimberly Potvin.

Amphetamine and amphetaminelike drugs have several legitimate clinical applications. Most nasal decongestants and diet pills are members of this family, as are the drugs used to treat narcolepsy, attention-deficit disorder, and attention-deficit/hyperactivity disorder (**FIGURE 23-6**).

Methamphetamine is problematic because it is a low-cost, long-acting (up to 12 hours) stimulant that is extremely addictive. Because the ingredients to cook methamphetamine are available locally within the United States and the drug is easily and quickly made, its manufacturer avoids the hassle, risk, and high cost associated with importing cocaine. “Meth labs” are dangerous and should be treated as a hazardous materials incident. In 2014, more than 9,000 incidents involving clandestine meth labs were reported by the US Drug Enforcement Agency;¹⁷ thus, AEMTs should be prepared to encounter these sites and take appropriate precautions when one is suspected, including calling for law enforcement and specialty responder assistance.

Synthetic cathinones, marketed as “bath salts” under unique names such as “Blaze,” have become a public health problem. These stimulants contain an active ingredient that is a pseudoephedrine (Sudafed) reduction drug called methcathinone, or a similar methamphetamine knock-off. Users typically snort, smoke, or ingest these drugs, which couple the intensity and long-acting effects of methamphetamine with the euphoric effects of crack cocaine. The more serious side effects of these designer drugs include agitation, hallucinations, and paranoia. Many states have now made it illegal

to manufacture or possess these drugs, which are often sold online. In addition, in 2012, the federal government banned the two main active ingredients of synthetic cathinones, mephedrone and methylenedioxypyrovalerone, although new compounds continue to emerge.¹⁸

Signs and symptoms of stimulant abuse may be noted in a patient who appears wild-eyed but thin as a rail, with nervous or jittery movements. For a serious abuser, week-long runs without sleeping are not unusual, and the person often goes days without eating during such a period. As the days pass by, increasing paranoia makes encounters risky. Patients are usually “amped up” when you encounter them, and it often takes very little to set off a violent tirade.

A person who has overdosed on cocaine may exhibit any of these signs and symptoms. Cocaine may also cause a variety of serious, potentially fatal complications: lethal cardiac dysrhythmias, acute myocardial infarction, seizures, stroke, apnea, and hyperthermia. In addition, a crack smoker risks pneumothorax and pneumomediastinum. The clinical presentation of the patient abusing amphetamine or methamphetamine is almost identical to that of a person abusing cocaine, except the effects last many hours longer than those of cocaine. Use of synthetic cathinones is associated with significant paranoia, hallucinations, incredible strength, excited delirium, and other bizarre behaviors. Tachycardia, diaphoresis, nausea, and hyperthermia may also be present. Pay careful attention to your personal safety when assessing and treating patients suspected of using these drugs.

The treatment for patients abusing cocaine, amphetamines, synthetic cathinones, or methamphetamine is fundamentally the same: maintain maximum oxygen saturation levels, prevent seizures with adequate sedation, and monitor serial vital signs. Consider paramedic backup for an advanced airway as needed. Establish vascular access and manage hypotension with a fluid infusion of normal saline. Apply the pulse oximeter. Call for paramedic backup to control anxiety and seizures and to administer benzodiazepines per local protocol. If the patient has a seizure, protect the airway. Finally, transport the patient to the appropriate facility.

In severe cases of stimulant overdose, the patient may present with hyperthermia, which can be lethal. Apply ice packs or mist the patient's skin to help reduce the body temperature.

Throughout the resuscitation process, it is essential to maintain peripheral perfusion with aggressive fluid therapy. Regular assessment of breath sounds to avoid inadvertent overhydration is necessary.

Remember the potential for the patient who has abused stimulants to be emotionally or psychologically unstable. With chronic abuse, each passing day without sleep and little or no food intake may make the patient increasingly paranoid and even psychotic. The patient's behavior can suddenly become violent, so consider the situation a potential hazard. Contact law enforcement for support when you first suspect the possibility that violence may occur.

Marijuana and Cannabis Compounds

When the leaves and flower buds of the *Cannabis sativa* plant are harvested and dried, the end product is referred to as **marijuana** (known as weed, pot, dope, smoke, and bud). Over the past decade, many states have legalized the use of marijuana and some of the compounds from the plant for medical use; some states have even legalized it for recreational use. According to the 2018 National Survey on Drug Use and Health, marijuana remains the most commonly used illicit drug in the United States, with approximately 35% of people ages 18 to 25 reporting using marijuana within the prior year.¹⁹ For these reasons, it is important to have a thorough understanding of marijuana and cannabis compounds.

Marijuana is usually smoked but can be ingested (such as when baked in cookies or brownies). The onset of effects from smoking marijuana occurs in a matter of minutes; oral ingestion slows the onset time to several hours.

Marijuana users may have a distorted sense of time and space and, occasionally, a feeling of unreality. Smoking marijuana results in bronchodilation and slight tachycardia. Other signs and symptoms of marijuana use include euphoria, drowsiness, decreased short-term memory, diminished motor coordination, increased appetite, and bloodshot eyes.

Management focuses on supportive care, because there is relatively low likelihood of a serious medical complication from marijuana use. A novice user may exhibit some behavioral symptoms such as paranoia and (rarely) psychosis. Reassurance is generally helpful with either issue.

Words of Wisdom

With the increased use of marijuana following legalization in some states, as well as an increase in the content of tetrahydrocannabinol (THC) in many marijuana products, ED visits relating to marijuana use have increased. Symptoms include tachycardia, uncontrolled emesis, and psychiatric issues.

Another illicit drug that is growing in popularity is **spice**, a mixture of dried plant material that is sold as incense in efforts to avoid existing drug laws. This psychoactive drug is a blend of synthetic cannabinoids (knock-offs of the naturally occurring psychoactive elements in marijuana), where the active substance is sprayed onto a plantlike material for smoking or sold as a liquid for vaporizing in e-cigarettes. Unlike marijuana, which typically has relaxing effects, the adverse effects of spice use include psychosis, hallucinations, tachycardia, vomiting, renal problems, and seizures. In some cases, these effects are reported to last as long as 3 months.

It can be challenging to obtain a good assessment and form a treatment plan for someone who has used spice. Remember that various chemicals may have been used in the spice, so you may be faced with patient presentations related more to those chemicals than to the plantlike material the patient is smoking. Supportive care with fluids and airway maintenance is often appropriate. Benzodiazepines are the recommended medication for patients experiencing a seizure. In these cases, call for paramedic backup to administer benzodiazepines or antiemetics.

Hallucinogens

A **hallucinogen** alters a person's sensory perception, causing the individual to see, hear, or feel things that are not actually present. Experiences involving hallucinogens can vary markedly, with people taking the same dose of the same drug from the same batch experiencing totally different effects. In 2018, 0.6% of Americans ages 12 years and older reported using hallucinogens in the past month; this rate has remained steady for more than 1 decade.²⁰

The classic hallucinogen is lysergic acid diethylamide (LSD). LSD primarily affects the senses rather than changing physiologic functions. Synesthesia

(crossing of the senses) often prompts a user to respond to the question "What were you doing?" with a reply such as "I was watching the music play" or "I was listening to that painting." With higher doses, the effects of LSD can last as long as 12 hours, although 3 to 4 hours is more typical. Effects of LSD often consist of tachycardia, mild hypertension, and dilated pupils. In a "bad trip," the user has a frightening experience, resulting in an acute anxiety attack and the physical effects secondary to increased anxiety.

Psilocybin mushrooms are among the most frequently used hallucinogens by teens and young adults in the United States (**FIGURE 23-7**).²¹ The onset of symptoms and hallucinogenic effects (similar to LSD but less intense) is within 30 minutes of ingestion, and effects usually last 4 to 6 hours. Signs and symptoms include nausea and vomiting, mydriasis, mild tachycardia, and mild hypertension. The likelihood of any serious medical side effects is low, though seizures and hyperthermia may occur.

Abuse of phencyclidine (PCP, angel dust), another hallucinogen, is relatively uncommon among young adults. Nevertheless, there were more than 75,000 ED visits related to PCP use in 2011 (up from 14,000 visits in 2005), with more than two-thirds of these visits involving men.²² PCP is typically smoked or snorted, although it can be injected.

FIGURE 23-7 Certain mushrooms are hallucinogenic if ingested.

© Elisa Locci/Shutterstock.

Slurred speech, staggering gait, tachycardia, hypertension, staring blankly for extended periods, and horizontal nystagmus (involuntary, rhythmic movement of the eyes) are common with PCP use. Muscle rigidity and especially grinding of the teeth prompt many users to resort to pacifiers in an effort to avoid pronounced jaw aches. More problematic are the hallmarks of PCP use, which include mind-body separation, related hallucinations, and violent outbreaks. Users may make bizarre comments such as “I can fly” and then jump off a balcony to prove it. Users have an almost unfathomable ability to withstand pain with no reaction and exhibit almost superhuman strength.

Ketamine (known as Special K, Vitamin K) is similar in chemical structure to PCP. Most ketamine available on the street is stolen from veterinary clinics, but this drug is increasingly being used in emergency medicine. Although its abuse in the general population is low (prevalence of recreational use in the US population is estimated between 0.1% and 4%), ketamine is a popular club drug used in nightclubs, raves, and other party settings. It is frequently used in combination with other club drugs, alcohol, and stimulants.²³ Ketamine and alcohol can work synergistically and is a risky combination. Illicit ketamine is colorless and odorless and is commonly found in powdered form. It is often mixed in a drink, although it can be snorted. It is physically and psychologically addicting.

Ketamine is a dissociative anesthetic. At low doses, a user presents with mild inebriation, lethargy, dreamy or erotic thoughts, and increased sociability. At higher doses, a patient may have pronounced nausea, difficulty moving, and report “entering another reality.” In extreme cases, users will enter the “K-hole,” which involves out-of-body experiences that may cause hallucinations, delusions, or a near-death experience.²⁴ Long-term use can result in extensive problems with memory, cognitive impairment, and/or an inability to properly speak or see.²⁵

Mescaline, the dried flower “buttons” of the peyote cactus, is also a hallucinogen. Peyote and mescaline are Schedule I substances with a high potential for abuse and no currently accepted medical use in the United States. Few statistics are available on their use. Profound vomiting occurs shortly after ingestion of mescaline. The psychedelic experience then typically begins with feelings of

increased sensitivity to sensory stimulation. Users may experience hallucinations, a distortion of time and space, or out-of-body experiences. The physical effects of mescaline are similar to those of LSD, including dilated pupils, increased heart rate, mild hypertension, and increased body temperature.

The treatment for a patient using hallucinogens is primarily supportive. A person having a bad trip is in a vivid dream or nightmare that will not end until the drug wears off. Try to limit sensory stimulation as much as possible; for example, avoid using emergency lights and siren. Routine transport to the appropriate facility plus psychological support is usually all that is required in the prehospital setting.

For patients who have used PCP or ketamine, secure the patient well, assess the ABCDEs and manage any life threats, administer oxygen therapy, establish vascular access if the patient is receptive, and provide safe transport to the appropriate facility. Keep a close eye on the patient, because violent behavior can suddenly occur. Benzodiazepines may help calm an agitated patient who is experiencing significant delirium; call for paramedic backup in such a case. *Note:* PCP can cause some of the most violent and difficult behavior you will encounter in the field, so protect the patient and the EMS team from attacks involving poor judgment and impaired behavior.

Care for mescaline users and psilocybin mushroom users is primarily supportive. Pay attention to the ABCDEs, administer oxygen therapy, monitor vital signs, provide positive psychological support, and provide safe transport. If time and circumstances allow, establish vascular access to provide a medication route.

Sedatives and Hypnotics

Sedative-hypnotic drugs have a wide range of applications. Drugs with sedative qualities reduce anxiety and calm agitated patients. Drugs with hypnotic qualities help produce drowsiness and sleep. In either case, sedative-hypnotic drugs function primarily as CNS depressants.

Barbiturates have a long history of use as sleep aids, antianxiety drugs, and seizure control medications. In the past, the frequent combination of alcohol and barbiturates used by people to attempt suicide and the high incidence of accidental overdoses pushed researchers to

develop sedative-hypnotic drugs that had fewer depressive effects on the respiratory system and were less lethal.

With mild to moderate barbiturate intoxication, patients present similarly to those with alcohol intoxication; their symptoms include drowsiness, decreased inhibitions, ataxia, mental confusion, and staggering gait. As the dose increases, patients become increasingly lethargic and demonstrate an increasingly lower level of responsiveness until they are unresponsive (Glasgow Coma Scale score of 3).

Barbiturate abusers quickly develop tolerance and require ever-larger doses to produce the desired effects. Long-term use results in physical addiction. Abrupt cessation in a long-term barbiturate abuser will produce typical signs and symptoms of withdrawal syndrome in approximately 24 hours. In the case of minor withdrawal, the patient may present with symptoms similar to those observed in a patient with alcohol withdrawal: restlessness, tremulousness, insomnia, diaphoresis, abdominal cramping, and nausea and vomiting. Patients in severe withdrawal may present with delirium, hallucinations, psychosis, hyperthermia, and cardiovascular collapse. Life-threatening withdrawal, similar to DTs, is possible with abrupt cessation of large doses of barbiturates.

Benzodiazepines are also members of the sedative-hypnotic family. These medications are most commonly used to treat anxiety, seizures, and alcohol withdrawal. Effects of benzodiazepines include sedation, reduced anxiety, and relaxation of striated muscle. Assessing a patient who is abusing benzodiazepines can be complicated, because the person is also likely to use other drugs and alcohol. The most common clinical effects of benzodiazepine overdose include altered mentation, drowsiness, confusion, slurred speech, ataxia, and general incoordination. The likelihood of death after the ingestion of a single sedative-hypnotic such as diazepam is small.

Withdrawal from benzodiazepines may include tachycardia, tremulousness, confusion, and possibly seizures. Withdrawal is rarely a life-threatening event, but it can be complicated by withdrawal from other substances, such as alcohol.

Airway management is the first priority in caring for a patient who has overdosed on barbiturates or benzodiazepines. Call for paramedic backup to intubate the patient and monitor the

electrocardiographic rhythm. Next, administer high-concentration oxygen and establish venous access. If the patient develops shock, then a rapid infusion of a 20-mL/kg bolus of normal saline and possibly repeated doses up to 2 L may be needed. Assess breath sounds before and after each bolus, rather than infusing an entire liter and then assessing breath sounds. A reversal agent (flumazenil [Romazicon], a benzodiazepine receptor antagonist) is available for managing a benzodiazepine overdose, although its use in the prehospital setting is rarely warranted, as it can precipitate withdrawal symptoms in susceptible patients. Call for paramedic backup for administration if needed.

Activated charcoal may also be an option for treating patients with sedative-hypnotic overdose. However, do not administer it to patients who are at risk of becoming unresponsive or of losing the ability to protect their airways, as vomiting can occur and aspiration of activated charcoal can be exceedingly dangerous.

Cardiac Medications

The medications used to treat patients with cardiac and cardiac-related problems continue to increase in number and sophistication. The major classes of drugs used as part of these treatment regimens include antidysrhythmics, beta-blockers, calcium channel blockers, cardiac glycosides, and angiotensin-converting enzyme inhibitors. Many patients take a combination of drugs (sometimes three or more) in attempts to control hypertension, electrocardiographic rhythm disturbances, or other problems. An overdose with these drugs is usually accidental.

Signs and symptoms of overdose with cardiac drugs vary, but may include hypotension, weakness or confusion, nausea and vomiting, rhythm disturbances (most commonly bradycardia or heart block), headache, and difficulty breathing. As with all emergencies, ensure a patent airway, provide adequate ventilation, and administer high-flow supplemental oxygen.

Establish vascular access in case of overdose with these agents. Several therapeutic interventions and antidotes are available if the specific agent is identified. In case of hypotension, sequential fluid boluses of normal saline will often bring the blood pressure into an acceptable range. Consider calling

for paramedic backup for advanced airway management and administration of vasopressors.

Because of the sophistication of cardiac drugs and the likelihood that the patient may be taking multiple cardiac and other medications, making contact with medical control to consult with a physician is prudent.

Other Medications

Erectile dysfunction medications are the most dangerous of the various drugs that increase sexual gratification. These drugs, such as sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra), are contraindicated for patients who take nitrates for cardiac conditions. In these patients, erectile dysfunction medications may result in severe hypotension or total cardiovascular collapse, ultimately leading to death. If patients develop hypotension after taking one of these drugs, then repeated boluses of normal saline can increase the blood pressure to an acceptable level. If cardiac arrest occurs, follow your protocols.

Patients taking a variety of psychiatric medications may experience toxicologic emergencies. **Tricyclic antidepressants (TCAs)** carry a high risk of intentional overdose. Also, minimal dosing errors

may produce toxic effects. The most common signs and symptoms of a TCA overdose are altered mental status (drowsy, confused, slurred speech), dysrhythmias (usually sinus tachycardia or supraventricular tachycardia), dry mouth, blurred vision or dilated pupils, urinary retention, constipation, and pulmonary edema. With a more serious toxic exposure, be alert for ventricular tachycardia, hypotension, respiratory depression, and seizures; dysrhythmias may be life threatening. Managing patients with a TCA overdose includes the following measures:

- Maintain the airway. If the patient's mental status suddenly deteriorates (as is often the case), insert an advanced airway.
- Call for paramedic backup as needed for cardiac monitoring, intubation, and medication administration.
- Administer high-flow supplemental oxygen as needed while monitoring SpO₂ and EtCO₂.
- Establish vascular access.
- Administer activated charcoal per medical control orders.
- Manage hypotension with sequential boluses of normal saline. Be alert to the possibility of pulmonary edema, which occurs frequently in cases of TCA overdose.

YOU are the Provider

Part 3

The patient's sister introduces herself and tells you her brother has used meth for about 5 years and has never sought drug treatment. You and your partner agree the patient requires transport to the ED via ambulance, and you also agree that law enforcement must ride in the back of the ambulance with you. When you speak with the police captain about this issue, he agrees to send one of his officers with you in the back, with another officer following the ambulance. Because the patient remains highly agitated and your department's policies prohibit patients from being handcuffed in the ambulance, with police assistance, you place each of the patient's extremities in soft restraints.

Recording Time: 4 Minutes

Respirations	32 breaths/min, rapid
Pulse	Strong and regular, 120 beats/min
Skin	Hot and dry
Blood pressure	84/52 mm Hg
Oxygen saturation (SpO ₂)	95% on room air
Pupils	Dilated, equal, and reactive to light

5. Which treatment does this patient require en route to the hospital?
6. Why should you have a law enforcement officer in the back of the ambulance during this transport?

- Assess blood glucose levels. Administer dextrose 50% in water if the patient is hypoglycemic.
- Rule out head trauma as a possible cause of decreased mental status.
- Monitor for agitation or violence. Provide rapid transport to the closest appropriate facility.

Monoamine oxidase inhibitors (MAOIs) are sometimes used to treat depression, but have a high potential for drug interactions. MAOIs can precipitate a hypertensive crisis if taken in conjunction with tyramine-containing foods (such as beer, wine, aged cheese, chopped liver, pickled herring, sour cream, yogurt, and fava beans). Symptoms of MAOI toxicity are often delayed, occurring 6 to 12 hours after ingestion and, in some cases, as long as 24 hours later. Once signs and symptoms begin to appear, you should prepare to manage a life-threatening event. Early signs and symptoms of MAOI overdose include hyperactivity, dysrhythmias (usually sinus tachycardia), hyperventilation, and nystagmus. With increased levels of toxicity, be alert for chest pain, palpitations, hypertension, diaphoresis, agitated or combative behavior, marked hyperthermia, and hallucinations.

Unfortunately, there is no antidote available for an MAOI overdose. Establish and maintain the airway. Administer high-flow supplemental oxygen or provide positive-pressure ventilation if needed. Establish vascular access. Consider administration of activated charcoal if recommended by medical control. Do *not* give syrup of ipecac. With a patient in deteriorating condition, treat hypotension with sequential fluid boluses of normal saline. If seizures occur, call for paramedic backup for medication administration.

Selective serotonin reuptake inhibitors (SSRIs) are among the widely used medications for managing depression. Patients with an SSRI overdose may be asymptomatic. When symptoms are present, they most commonly include nausea, vomiting, dysrhythmias (usually sinus tachycardia), sedation, and tremors, and possibly dilated pupils, agitation, blood pressure changes (hypotension or hypertension), seizures, and hallucinations. Treating a patient with an SSRI overdose follows the general approach for poisoned patients:

- Establish and maintain the airway.
- Administer high-flow supplemental oxygen.
- Establish vascular access.

- Call for paramedic backup as needed.
- Consider a single dose of activated charcoal per medical control.
- Transport the patient to the appropriate facility.

Despite the major advances made in many areas of psychiatric medicine, **lithium** remains the cornerstone drug for treating a bipolar disorder. Lithium is excreted from the body slowly, meaning the threat of toxic levels and overdosing is always present. Signs and symptoms of lithium overdose include nausea, vomiting, hand tremors, excessive thirst, and slurred speech; as toxicity increases, patients may develop ataxia, muscle weakness and incoordination, blurred vision, and hyperreflexia (twitching). Eventually, patients may have seizures and become comatose.

Managing a patient with a suspected lithium overdose is mostly supportive. Establish and maintain the airway, inserting an advanced airway as needed. Administer high-flow supplemental oxygen, and ensure vascular access. If the patient experiences hypotension, administer serial boluses of normal saline. Transport the patient to an appropriate facility.

Medications used for pain management account for a large portion of the over-the-counter (OTC) drug market. Nonsteroidal anti-inflammatory drugs (NSAIDs) are some of the most popular options for pain relief, fever control, and anti-inflammatory action. Most of the problems associated with NSAIDs involve long-term use; patients may experience gastrointestinal bleeding and kidney dysfunction with chronic use. Signs and symptoms of NSAID overdose may include headache, altered mentation, behavioral changes, seizures, bradydysrhythmias, hypotension, abdominal pain, nausea, and vomiting.

For symptomatic patients with NSAID overdose, care in the prehospital setting is usually supportive. Establish and maintain the airway, inserting an advanced airway as needed. Administer high-flow supplemental oxygen, and establish vascular access. If hypotension develops, administer fluid boluses of normal saline. If hypotension persists after sequential fluid boluses, consider calling for paramedic backup for medication administration. Transport the patient to an appropriate facility.

Although aspirin (acetylsalicylic acid [ASA]) can be involved in a toxicologic emergency, more

typically other OTC products containing **salicylates** cause toxicity (eg, Pepto-Bismol and hot-air vaporizers). With continued use of these products over a period of days, infants or young toddlers may ingest toxic levels of the salicylate. Chief complaints are usually nausea, vomiting, abdominal pain, diaphoresis, hyperpnea, ringing in the ears, pulmonary edema, and acid-base disturbances. Severe toxicity may produce metabolic acidosis or combined respiratory alkalosis–metabolic acidosis.

No salicylate antidote or antagonist is available, so field management is primarily supportive. Establish and maintain the airway, inserting an advanced airway as needed. Administer high-flow supplemental oxygen and establish vascular access. If hypotension develops (from volume depletion), administer serial boluses of normal saline. Monitor carbon dioxide levels with capnometry if available. Following consultation with medical control, administer one dose of activated charcoal if appropriate. Call for paramedic backup as needed. Transport the patient to the closest, most appropriate facility.

Acetaminophen is a well-tolerated drug with few side effects that is available OTC. It is important to try to accurately estimate the time of its ingestion, because this information drives the decision-making process for patient care in the field and the hospital following acetaminophen overdose. An antidote for acetaminophen toxicity exists, although not as a prehospital intervention, and should be given less than 8 hours after the ingestion.

Prehospital management of acetaminophen toxicity first focuses on establishing and maintaining the airway, with an advanced airway being inserted as needed. Administer high-flow supplemental oxygen, and establish vascular access. For recent ingestions, consider administration of activated charcoal after consulting with medical control, and only if the patient is alert and able to follow commands. Transport the patient to an appropriate facility.

Drugs used to facilitate sexual assault, commonly known as “date rape” drugs, are often administered unknowingly to an individual, frequently in an alcoholic drink. **Gamma-hydroxybutyrate (GHB)** is a drug that is frequently associated with sexual assaults. GHB is available as an odorless and colorless liquid. It has a salty taste, but this may not be noted when placed in a drink. GHB produces a pronounced hypnotic effect along with disinhibition,

severe passivity, and anterograde amnesia. Treatment for GHB intoxication focuses on the CNS depression and the risks associated with the patient being unable to protect the airway. Establish and maintain the airway; insert an advanced airway as needed. Carefully monitor the patient’s level of consciousness. Assist breathing as necessary and administer high-flow supplemental oxygen. Establish vascular access. Apply the pulse oximeter. Finally, provide rapid transport to the ED.

Organophosphates

Organophosphates are a major component in many insecticides (Orthene, diazinon, and malathion) used in agriculture and in the home. Similar-performing compounds are used as “nerve gases” designed for chemical warfare, and like organophosphates, are categorized as cholinergic agents. These agents overstimulate normal body functions that are controlled by the parasympathetic nerves, resulting in salivation, mucus secretion, urination, lacrimation, and an abnormal heart rate. You are unlikely to encounter patients who have been exposed to nerve gases, but you may be called to care for patients who have been exposed to one of the organophosphate insecticides (pesticides) or certain wild mushrooms, which are also cholinergic agents.

Suicide attempts account for a considerable share of organophosphate poisonings. When suicide is the goal, the poison is usually taken by mouth. Accidental agricultural exposure is another common source of AEMT calls for organophosphate poisoning, and persons involved in the manufacture of organophosphates and similar compounds are all at risk for this type of exposure.

The symptoms of organophosphate poisoning are fundamentally the same regardless of the chemical’s route of entry: anxiety and restlessness; headache, dizziness, and confusion; tremors or seizures; dyspnea, diffuse wheezing, and respiratory depression; and loss of consciousness. A patient poisoned with organophosphates will usually present with signs and symptoms within the first 8 hours. In addition, the CNS signs and symptoms associated with cholinergic excess are often expressed using the SLUDGEM mnemonic:

S Salivation, sweating

L Lacrimation (excessive tearing of the eyes)

- U** Urination
- D** Defecation
- G** Gastric upset and cramps
- E** Emesis
- M** Muscle twitching/miosis (pinpoint pupils)

Alternatively, you can use the mnemonic DUMBELS:

- D** Diarrhea
- U** Urination
- M** Miosis (constriction of the pupils), muscle weakness
- B** Bradycardia, bronchospasm, bronchorrhea (discharge of mucus from the lungs)
- E** Emesis
- L** Lacrimation
- S** Seizures, salivation, sweating

To assess and treat a patient with organophosphate poisoning, start with decontaminating and removing all contaminated clothing *before* initiating care or loading the patient into the ambulance. Contaminated clothing should be placed in plastic bags and disposed of as hazardous materials. Ideally, the patient should be scrubbed with soap and water. After that, patient care includes the following measures:

- Establish and maintain the airway. Consider an advanced airway as needed.
- Suction as needed.
- Administer high-flow supplemental oxygen.
- Establish vascular access.
- Call for paramedic backup for medication administration and cardiac monitoring.
- Apply the pulse oximeter and ETCO_2 .
- Transport immediately to the closest appropriate facility and notify the receiving facility of the possibility of a contaminated patient.

In the unlikely event of a terrorist attack involving cholinergic agents, be aware that the US military has developed antidotes to nerve gas agents that can be administered if they are available and indicated. The most common of these antidotes are the DuoDote kit, the Antidote Treatment Nerve Agent Auto-Injector (ATNAA), and the Mark 1 kit (which is no longer manufactured but may still be present in stocked supplies). The indications for these antidotes are a known exposure to nerve agents or organophosphates with manifestation of signs and symptoms. Removal of the patient from the source

of the exposure is also critical in these cases. If your service carries these antidote kits, ask to receive training on the proper use prior to being cleared to administer them. Nerve agent treatment, and these kits, are covered in Chapter 42, *Terrorism Response and Disaster Management*.

Carbon Monoxide

Carbon monoxide is one of the most common fatal poisonings.²⁶ This gas is produced during the incomplete combustion of organic fuels, such as in an automobile engine or a home-heating device. CO poisoning may occur when a flue or ventilating system becomes blocked, or it may be a method of suicide (an automobile running in a closed garage). CO is also a major contributor to death in house fires.

Because CO is a colorless, odorless, tasteless gas, people who are exposed to it often have no idea that they are inhaling a toxic substance until it is too late. The toxicity arises primarily from the affinity of CO for hemoglobin in red blood cells; carbon dioxide displaces oxygen, thereby preventing the red blood cells from carrying oxygen to the tissues and leading to suffocation at the cellular level. The atmospheric level of CO does not need to be very high for poisoning to occur.

Because the overall ability of the blood to transport oxygen is drastically reduced when CO reaches toxic levels, anything that increases the body's oxygen requirements, such as physical exertion or a fever, will increase the severity of the poisoning. Children, whose metabolic rate is intrinsically higher than that of adults, tend to have more severe symptoms at any given level of exposure.

CO poisoning can be difficult to diagnose in the field unless it is the direct result of an easily identifiable cause, such as a fire or intentional exposure to exhaust fumes from an automobile. Its signs and symptoms are highly variable and vague, often resembling the early onset of the flu—for example, headache, nausea, and vomiting. With acute poisoning, the patient may be confused and unable to think clearly. Complaints of a sensation of pressure in the head or roaring in the ears are common. The physical exam often reveals bounding pulses, dilated pupils, and pallor or cyanosis. The cherry red color of the skin that is mentioned in many textbooks is a very late sign of CO poisoning. Consider the possibility of CO poisoning whenever you

are confronted with several (possibly many) people who have shared the same accommodations for any period, especially if they have been quartered together in a closed area, such as one house in the winter.

Words of Wisdom

Carbon monoxide is a hazard for providers, as well as for patients. When you have multiple patients with medical complaints—at the same time and inside the same building—consider CO poisoning.

Recent developments in technology have given AEMTs the ability to perform noninvasive identification of CO poisoning (% SpCO, or CO saturation of the blood) in the field, which helps address the problem of delayed diagnosis. *Note:* Pulse oximetry *will not* provide a true assessment of arterial oxygenation because the device cannot determine whether CO or oxygen is bound to the hemoglobin. A reading of 99% on the pulse oximeter would be excellent in a normal environmental setting, but would be a grave finding in the presence of carboxyhemoglobin because the hemoglobin is saturated with the wrong chemical! Special CO monitoring devices are available that use the same probe used to measure oxygen saturation, but specifically measure CO saturation instead. If your service carries a CO monitoring device, ensure you know how to use it.

Treat CO poisoning in the field by administering the highest concentration of oxygen possible in an attempt to displace CO molecules from the hemoglobin. For patients with only mild symptoms, such as headache, nausea, and flulike symptoms, the elimination half-time of carboxyhemoglobin is roughly 4 hours. By comparison, if the patient is breathing 100% oxygen, the half-time can be reduced to approximately 1.5 hours. Hyperbaric oxygen therapy can further reduce the elimination time in some cases of severe exposure with markedly elevated CO levels.

If you suspect CO poisoning:

- Remove the patient from the exposure environment.
- Establish and maintain the airway, inserting an advanced airway as needed.

- Administer high-flow supplemental oxygen by a tight-fitting nonrebreathing mask.
- Establish vascular access.
- Keep the patient quiet and at rest to minimize oxygen demand.
- Monitor the patient's level of consciousness.
- Transport the patient to the appropriate facility. If the patient is unresponsive or has signs of serious CO poisoning, then direct transport to a facility capable of providing hyperbaric medicine is preferred.
- For patients with injuries or illness from a structural or vehicular fire, consider the possibility of combined CO/cyanide poisoning, especially if the patient has signs of shock.

Metals

Despite the bans on lead in gasoline, paint, canning processes, and plumbing, lead poisoning remains the leading cause of chronic metal poisoning.²⁷ It has long been known that elevated levels of lead exposure may significantly hamper intellectual development in children.

With inorganic lead, absorption usually occurs via the respiratory or gastrointestinal tract. Once inside the body, approximately 90% of the lead is stored in the teeth and bones.²⁸ From this site, it eventually makes its way into the bloodstream. Inorganic lead can also cross the placental barrier and negatively affect fetal development. Its excretion from the body is incredibly slow, with the half-life of lead in bone estimated at 30 years.

Most organic lead (tetraethyl lead) exposures occur in occupational settings,²⁹ although they can also occur from gas sniffing where leaded gasoline is available. Once inside the body, tetraethyl lead is metabolized to inorganic lead and triethyl lead, with triethyl lead being the primary cause of CNS toxicity.

Lead poisoning is associated with a long list of signs and symptoms (**TABLE 23-4**). In particular, encephalopathy is a major cause of mortality and morbidity from lead poisoning.

In the field, you have few treatment options for lead poisoning. Your most helpful move may be to identify the source of the lead, which can assist the appropriate government agency to prevent more occurrences by removing the toxin. When you are managing the patient, first establish and maintain

TABLE 23-4 Body Systems Affected by Lead Poisoning

Body System	Signs and Symptoms
Central nervous	Altered mentation, including irritability, mood changes, memory deficit, sleep disturbances; headache; seizures; ataxia
Gastrointestinal	Abdominal pain (usually occurs with acute poisoning); constipation; diarrhea
Renal	Renal insufficiency; hypertension; gout
Hematologic	Anemia

© Jones & Bartlett Learning.

the airway, inserting an advanced airway as needed. Administer high-flow supplemental oxygen. Establish vascular access with a saline or heparin lock. Unless hypotension is present, do not provide fluid therapy as it may worsen cerebral edema. Transport the patient to an appropriate facility.

Iron is another metal that is commonly ingested. Although only a small amount of iron is required as part of a healthy diet, many adult and pediatric multivitamins contain iron. Children younger than 6 years have frequent iron exposures, usually secondary to ingesting chewable vitamins that are flavored or in cartoon shapes. By comparison, most toxic exposures in adults are intentional.

In the average 154-pound (70-kg) adult, the body's entire iron supply consists of only about 4 g. Of that total, roughly 65% is found in hemoglobin, with the remainder sequestered elsewhere. Because of its toxic potential, iron is stored in the body by several mechanisms, which permit access to the supply as needed. The body of a healthy person does not contain free (unbound) iron.

From a practical perspective, the toxic effects of an iron exposure reflect the amount of elemental iron ingested. You should expect mild to moderate toxicity if a patient ingests 20 to 60 mg/kg. With dosing of more than 60 mg/kg, severe and potentially lethal toxicity is a possibility.

Two broad categories of iron poisoning can be distinguished: gastrointestinal and systemic. With gastrointestinal toxicity, the symptoms consist of

abdominal pain, vomiting (the most common sign), and diarrhea. With systemic toxicity, patients may be hypotensive or in frank shock from coagulopathy and vomiting blood. These patients are commonly in metabolic acidosis and become tachypneic as the body attempts to adjust its pH by increasing the elimination of carbon dioxide.

Children typically remain asymptomatic when they have a low-level iron exposure. However, children who ingest a large dose of iron are at risk of dying unless aggressive and immediate interventions are taken. Unfortunately, there is little you can do in the field for iron poisoning, other than provide basic attention to the ABCs and transport the patient to the closest, most appropriate facility for further evaluation and laboratory studies.

Special Populations

Children younger than 6 years have frequent iron exposures, usually secondary to ingesting chewable vitamins. Children typically remain asymptomatic when they have a low-level iron exposure. However, children who ingest a large dose of iron are at risk of dying unless aggressive and timely interventions take place. Unfortunately, little can be done in the field for iron poisoning, other than providing basic attention to the ABCs and transporting the patient to the closest, most appropriate facility for further evaluation and laboratory studies.

Miscellaneous Substances

Many other substances may cause toxicologic emergencies. Additional substances are discussed in this section.

Incidents involving chlorine gas are relatively common because of the widespread use of chlorine compounds in the home and occupational settings. Cases of chlorine gas exposure occur both inside (eg, from mixing bleach and other cleaning products) and outside the home. The signs and symptoms of chlorine gas exposure include burning sensations in the eyes, nose, and throat along with a slight cough. With a more intense exposure, patients may develop chest tightness, sensation of choking, paroxysmal cough, headache, nausea and vomiting, diffuse wheezing, cyanosis, crackles in the chest, shock, seizures, and loss of consciousness. Remove patients from the area of exposure.

Once you are in a safe environment, quickly triage the patients, prioritizing those with breathing problems. Irrigate burning or itching eyes with water, as well as any areas of the skin that have come in contact with the chlorine.

Cyanide poisoning can occur as a result of combustion of certain materials in a fire, through industrial exposure, or after ingestion of products that contain cyanide. Within the body, cyanide blocks the utilization of oxygen at the cellular level. The results are cellular suffocation and death of the patient within seconds if the cyanide was inhaled or within minutes to possibly an hour or two if it was ingested. A patient who has been poisoned with cyanide may have an altered mental state. Patients who are alert enough to answer questions may report headache, palpitations, or dyspnea. A classic odor of bitter almonds on the patient's breath is highly suggestive of cyanide poisoning. Initially, respirations are usually rapid and labored; however, as the poisoning progresses, respirations can become slow and gasping. The pulse is usually rapid and thready. Vomiting, seizures, and coma are common. Treatment must be instituted as fast as possible. Administer 100% oxygen via nonrebreathing mask or positive-pressure ventilations. In the prehospital setting, hydroxocobalamin or sodium thiosulfate may be ordered by medical control to counteract cyanide; if it is given in time, this treatment is usually effective. Call for paramedic backup if needed for advanced airway management or treatment of seizures. Notify the receiving hospital of the probable diagnosis so staff can make preparations. Transport the patient without delay to an appropriate facility.

Caustics include strong acids and strong alkalis. Both types of chemicals are commonly used in industry, agriculture (anhydrous ammonia), and the home (eg, bleach). Most cases of caustic poisoning involve accidental dermal or ocular exposure. If the patient is an adult, oral ingestion of caustics is usually an intentional suicide attempt. Most patients who have swallowed caustic substances present with severe pain in the mouth, throat, or chest. Usually, the airway is not a problem and the patient is not in shock. Respiratory distress, if present, is most likely due to soft-tissue swelling in the larynx, epiglottitis, or vocal cords, which means that the patient is in immediate danger of complete airway

obstruction. Establish vascular access, usually en route, because immediate transport to the ED is needed. If the patient was exposed to a strong alkali, diluting and flushing away the caustic substance is the main goal. With an eye exposure, continuously irrigate the eyes; if only one eye was exposed, ensure you do not contaminate the other eye while washing.

Words of Wisdom

There are a number of significant "don'ts" for caustic ingestions: *don't* give any neutralizing substances, *don't* induce vomiting, *don't* perform gastric lavage, and *don't* give activated charcoal.

Some alcohols, including methyl alcohol and ethylene glycol, are even more toxic than ethyl alcohol (drinking alcohol). Methyl alcohol is found in dry gas products and Sterno; ethylene glycol is found in some antifreeze products. Both cause a "drunken" feeling. If patients are not treated for ingestion of these alcohols, both will also cause severe tachypnea, blindness (methyl alcohol), renal failure

Safety

Some chemicals react with water. Although small amounts can usually be flushed safely with large quantities of water, larger amounts of such chemicals can give off toxic fumes or explode when wet. Ensure you check the relevant warnings or placards or call poison control for assistance.

Words of Wisdom

Many poisonous items are commonly found in households. For example, many household cleaning agents are toxic if ingested. Laundry pods are especially troubling because small children are often attracted to their small size and bright colors. Household plants may have poisonous leaves or berries. Pesticides and herbicides used in lawn and garden care are potentially poisonous. Paint thinners and solvents can cause permanent neurologic damage or death if inhaled in the right amount; the same is true of glue fumes.

(ethylene glycol), and eventually death. Although they may be used as a substitute by a chronic alcoholic who is unable to obtain ethyl alcohol, these types of alcohols are more often taken by someone attempting suicide. Even ethyl alcohol can stop a patient's breathing if taken too fast or in a dose that is too high, particularly in children. In either case, immediate transport to the ED is essential.

Hydrocarbons are found in a variety of products around the home, including cleaning and polishing agents, glues, spot removers, lighter fluids, paints, paint thinners and paint removers, other fuels, and pesticides. Most intentional hydrocarbon inhalations are “recreational,” but hydrocarbons may also be ingested by young children who mistake them for a beverage. Hydrocarbon inhalation is achieved by pouring the volatile material onto a rag, placing it in a trash bag, and then holding the bag over the face to breathe in the fumes. Breathing fumes directly off a soaked rag or towel is termed *huffing*, whereas the use of a trash bag is called *bagging*. Frequently, people who “bag” or “huff” are young—middle-school age and, occasionally, younger children. A single hydrocarbon substance exposure

may cause life-threatening toxicity and, on occasion, sudden death.

Treat a patient who has inhaled hydrocarbons by removing the patient from the noxious environment, administering high-concentration supplemental oxygen, and promptly transporting to the appropriate facility. Patients who have symptoms such as coughing, choking, or vomiting within a few minutes of ingestion are likely to have aspirated and need immediate attention. Signs of respiratory distress—air hunger, intercostal retractions, tachypnea, and cyanosis—must be considered danger signals. Hypoglycemia and cardiac dysrhythmias may occur; call for paramedic backup if needed. The patient may have severe abdominal pain, diarrhea, and belching, sometimes lasting for hours after the incident. Management should include the following measures:

- Remove contaminated clothing and decontaminate the patient, ideally before placing the patient in the ambulance.
- Establish and maintain the airway, and ensure adequate ventilation.

YOU are the Provider

Part 4

As your partner initiates transport to the local hospital, you administer 100% oxygen to the patient via a nonrebreathing mask and establish IV access with an 18-gauge catheter. You decide to administer a 20-mL/kg bolus of normal saline in an attempt to increase his blood pressure, and you apply ice packs in the axillary regions to cool the patient down. As you are attempting to clean and bandage the abrasions on the patient's arms, he continually tries to pull away and get out of the restraints. The remainder of your transport remains uneventful, and on arrival at the ED, you turn over care to the staff without incident.

Recording Time: 12 Minutes

Respirations	30 breaths/min, rapid
Pulse	Strong and regular, 118 beats/min
Skin	Hot and dry
Blood pressure	102/74 mm Hg
Oxygen saturation (SpO₂)	98% on 100% oxygen
Pupils	Dilated, equal, and reactive to light

7. What are the possible complications of use of restraints?
8. Should you be concerned about the possibility of infectious disease in this patient?

- Administer high-flow supplemental oxygen.
- Establish vascular access.
- Administer sequential bolus infusions of normal saline to treat hypotension.
- Transport the patient to the most appropriate facility.

Food Poisoning

Whenever you encounter two or more people who are sick at the same time and at the same scene, think food poisoning or CO poisoning—your hunch will likely be correct.

Four pathogens are the leading causes of food-related deaths in the United States: *Salmonella* (28%), *Toxoplasma* (24%), *Listeria* (19%), and norovirus (11%).³⁰ Poisoning with *Clostridium botulinum*, an extremely deadly toxin, is usually the result of improper food storage or canning. In addition, the toxins produced by dinoflagellates in “red tides” may contaminate bivalve shellfish such as oysters, clams, and mussels and produce life-threatening or fatal paralytic shellfish poisoning.

Depending on the toxin, onset of signs and symptoms can range from several hours after ingestion to days or weeks. The longer the time until symptom onset, the more difficult it will be to link the patient’s problem to the event at which the toxin was ingested. Gastrointestinal complaints are the most common and include abdominal pain and cramping, nausea, vomiting, and diarrhea. With prolonged episodes of vomiting or diarrhea, hypotension secondary to fluid loss and electrolyte imbalance becomes likely. Respiratory distress or arrest can occur with toxins such as *C. botulinum* or those found in paralytic shellfish poisoning.

Treatment for patients with food poisoning is usually supportive. Most of the cases you will encounter will not be life threatening, and the signs

and symptoms of acute gastroenteritis are typically self-limiting. Establish and maintain the airway, inserting an advanced airway as needed. Administer high-flow supplemental oxygen and establish vascular access. For hypotension secondary to fluid loss, administer fluid boluses of normal saline. Call for paramedic backup as needed. Finally, transport the patient to an appropriate facility.

Poisonous Plants

Of the thousands of plant varieties, only a few are poisonous (**FIGURE 23-8**). Oddly enough, poisonous plants represent some of the most common ornamental garden shrubs and houseplants. Most plant-related exposures involve children younger than 6 years; over 24,000 such incidents were reported to US poison control centers in 2018.³² Deaths from plant ingestions are rare, however.

TABLE 23-5 lists common toxic plants.

Some poisonous plants cause local irritation of the skin; others can affect the circulatory system, the gastrointestinal tract, or the CNS. It is impossible for you to memorize every plant and poison, let alone their effects, but there are two worth mentioning.

The ubiquitous **dieffenbachia** is a green plant with broad, variegated leaves that resemble an elephant’s ear. It is nicknamed “dumb cane” because eating dieffenbachia can result in a person being unable to speak. In severe cases, edema of the tongue and larynx may lead to airway compromise. Dieffenbachia ingestion is common in children and cats.

Castor bean seeds originate from an attractive shrub but are highly poisonous; chewing on just a few seeds (and, in some cases, just one) can kill a child. Ricin, the poison in castor beans, causes a variety of toxic effects: burning of the mouth and throat; nausea, vomiting, diarrhea, and severe stomach pains; prostration; failing vision; and kidney failure (the usual cause of death).

When you encounter a case of plant poisoning, get all the information you can from the patient or parent and then consult your regional poison center for advice:

- **When was the plant ingested?** If it was more than 12 hours ago and the patient is still asymptomatic, chances are good that the patient will not experience symptoms. Most plant

Words of Wisdom

Herbal preparations can cause potentially serious interactions with traditional medications and, in some cases, overdose.³¹ Ensure you inquire about all medications the patient may have taken, including herbal medications or supplements.

FIGURE 23-8 The toxins in these common poisonous plants are often ingested or absorbed through the skin.

TABLE 23-5 Common Toxic Plants

Scientific Name	Common Name
<i>Abrus precatorius</i>	Jequirity bean/rosary pea
<i>Cicuta</i> species	Water hemlock/wild carrot
<i>Colchicum autumnale</i>	Autumn crocus
<i>Conium maculatum</i>	Poison hemlock
<i>Convallaria majalis</i>	Lily of the valley
<i>Datura stramonium</i>	Jimsonweed/stinkweed
<i>Dieffenbachia</i>	Dumb cane
<i>Digitalis purpurea</i>	Foxglove
<i>Nerium oleander</i>	Oleander or rose laurel
<i>Nicotiana glauca</i>	Tree tobacco
<i>Phoradendron</i>	Mistletoe
<i>Phytolacca americana</i>	Pokeweed
<i>Rhododendron</i>	Rhododendron or azalea
<i>Ricinus communis</i>	Castor bean/ricin
<i>Solanum nigrum</i>	Deadly nightshade/atropa belladonna
<i>Zigadenus species</i>	Death camas

Data from: National Poison Control Center. Poisonous and non-poisonous plants. <https://www.poison.org/articles/plant>. Accessed August 25, 2020.

poisonings produce signs and symptoms of toxicity, if they are going to do so, within 4 hours of ingestion. One notable exception is castor bean, for which symptoms may not appear until 1 to 3 days after ingestion.

- **What, exactly, was eaten?** Try to find out not just which type of plant, but also which parts of the plant (eg, leaves, root, stem, flower, or fruit) were eaten. If possible, estimate how much was ingested (such as a bite or two from a leaf versus three or four leaves). If you transport the patient, take along the offending plant, or whatever is left of it.
- **Which signs or symptoms, if any, does the patient have?** Most plant-related exposures require no treatment, a decision that can be made after consulting with the poison center and medical control per local protocol. If there is a responsible adult who can keep a close eye on the child for at least 4 to 6 hours after the ingestion, there is no need to transport the child to the hospital. Conversely, a child with any signs and symptoms should be evaluated in the ED.

Emergency medical treatment of dieffenbachia poisoning includes maintaining an open airway, administering oxygen, and promptly transporting the patient to the closest hospital for respiratory support. Continue to assess the patient for airway difficulties throughout transport. If necessary, provide positive-pressure ventilation.

YOU are the Provider SUMMARY

1. What are the potential hazards with this scene?

This scene presents numerous hazards for EMS, law enforcement, and the patient, as well as any additional bystanders. This is a highly volatile situation with a patient who is not obeying commands by law enforcement, and could easily escalate. It is imperative that EMS providers remain in a safe staging area away from potentially unsafe areas to minimize the potential for injury.

2. What is a likely explanation for this patient's presentation?

A multitude of reasons might have led to this patient's presentation. The most likely explanation is the patient is experiencing an acute psychotic

episode. Other possibilities for his behavior include agitated delirium, drug or alcohol withdrawal, or drug abuse.

3. Does this patient's presentation warrant transport via EMS, or should he be transported via law enforcement?

This patient definitely requires transport via EMS. He is experiencing an altered mental status for an unknown reason. Also, he has abrasions to his arms with active bleeding; this medical problem rules out the option of transport via law enforcement. There is also the possibility that the patient might experience a seizure, which would be better managed by an AEMT.

YOU are the Provider SUMMARY *continued***4. Should you request paramedic backup for this patient?**

Whether you request paramedic backup depends on your system's policies and procedures. Presently, this patient does not require any skills that would mandate the presence of a paramedic. However, if the patient's condition deteriorates at any point, paramedic backup should be requested.

5. Which treatment does this patient require en route to the hospital?

This patient requires supportive care. Obviously, the bleeding needs to be controlled and the wounds dressed. An IV line should be established and a fluid bolus administered in an attempt to increase his blood pressure. Administer oxygen to prevent hypoxia, and ice packs should be applied to promote cooling of the core temperature.

6. Why should you have a law enforcement officer in the back of the ambulance during this transport?

Depending on system policies and procedures, law enforcement may be required whenever a patient has been placed in handcuffs. Regardless of policies,

having a law enforcement officer in the back of the ambulance lessens the potential for injury for EMS providers should the patient get out of his restraints and become a threat.

7. What are the possible complications of use of restraints?

The potential complications of use of restraints include loss of distal circulation if the restraints are applied too tightly. That is the conundrum: if restraints are applied too tightly, distal circulation is lost; if they are applied too loosely, the patient may be able to become free from the restraints. Also, depending on the degree of compliance of the patient, there is a potential for injury from fractures or strains if the patient continues to struggle.

8. Should you be concerned about the possibility of infectious disease in this patient?

Yes. Whenever blood or body fluids are present on a patient, there is the potential for transmission of infectious disease. In this scenario, the patient's history of drug use exponentially increases the possibility for infectious disease.

Narrative

EMS dispatched to above location for “unknown medical, police request.” On arrival, spoke with the Captain of the Police Dept, who states they received multiple reports of a “naked person covered in blood, acting bizarre.” The patient can be seen standing in the front yard of a residence, with both arms covered in blood, yelling incoherently. The Captain states they will probably have to physically subdue the patient, and to stand by for further orders. After approximately 20 minutes on scene, law enforcement subdued the patient and subsequently placed him in handcuffs. After we were directed to the patient, the patient’s sister arrived on scene.

The patient presents as alert, but unable to give us any additional information. Airway is patent, minimal bleeding noted to each forearm, appears to be abrasions. Patient remains screaming at the top of his lungs, “Don’t let them get me. I’m burning. God help me.” Patient’s sister provides medical history of 5 years of methamphetamine use. With law enforcement assistance, handcuffs were removed and each of patient’s extremities placed in soft restraints. Transport initiated to North Regional Medical Center with patrolman Steele accompanying in back of ambulance. 100% oxygen via a nonrebreathing mask administered. 18-gauge IV line with 20-mL/kg bolus of 0.9% normal saline administered. Ice pack applied to axillary regions, and abrasions cleaned and bandaged. Patient remains agitated and hostile throughout transport. Distal circulation checked numerous times, with +PMS to all extremities. On arrival at NRM, care and report given to ED staff without incident.

End of report

Prep Kit**Ready for Review**

- Toxicologic emergencies usually fall under one of two general headings: intentional or unintentional.
- Even the most well-read veteran AEMT may find it difficult to stay up-to-date with the myriad drugs sold in the streets today. For this reason, poison centers may be an indispensable aid in a suspected toxicologic emergency.
- The four primary methods whereby a toxin commonly enters the body are ingestion, inhalation, injection, and absorption.
- Although the sheer number of substances of abuse may seem daunting, many drugs, on entering the body, result in similar signs and symptoms. The syndromelike symptoms of a poisonous agent are termed a toxic syndrome or toxidrome. The major toxidromes are produced by stimulants, opioids, sympathomimetics, sedatives and hypnotics, cholinergics, and anticholinergics.
- Substance abuse is self-administration of licit or illicit substances in a manner not in accordance with approved medical or social practice. A person may become physically or psychologically dependent on a substance through this practice and develop a tolerance.
- People who are addicted to a substance can experience withdrawal syndrome (a predictable set of signs and symptoms) if they abruptly stop using a drug or rapidly decrease the usual dosage.
- Toxicologic emergency scenes can present hazards to the AEMT, including potential contamination with the substance or potentially dangerous patients. AEMTs must properly

protect themselves and thoroughly assess every scene before entering it.

- Generally, patients with toxicologic emergencies are considered medical patients, although toxicologic emergencies may lead to trauma, too.
- At the scene of a potential toxicologic emergency, look for clues that might indicate that a substance or poison is involved, such as medication bottles, alcoholic beverage containers, syringes, drug paraphernalia, or an unusual odor.
- Managing the ABCs is the top priority with toxicologic patients, as always. Have suction available, as these patients are susceptible to vomiting.
- Consider decontamination of the patient before transport depending on the poison to which the patient was exposed. In some cases, a patient may need to be decontaminated prior to assessment and treatment by specially trained and equipped personnel.
- Ask which agent the patient was exposed to, when the patient was exposed to it, how much of the substance was involved, whether anything else was taken, over what time period the patient was exposed to the substance, whether any interventions were performed, how much the patient weighs, and why the substance was taken. Also find out if the patient has vomited or aspirated and why the substance was taken.
- Transport any containers, the remainder of the substance, and vomit with the patient, if possible, for identification.
- The condition of patients exposed to poisons may change suddenly and without warning. Continually reassess the ABCDEs and repeatedly obtain vital signs. If the poison or the level of exposure is unknown, careful and frequent reassessment is required.
- The treatment for poisoned patients depends a great deal on the toxin, the route of exposure, and other signs and symptoms found in your assessment.
- Emergency medical care for a patient with a toxicologic emergency includes ensuring scene safety, managing the ABCs, administering oxygen, establishing vascular access, and being prepared to manage shock, coma, seizures, and dysrhythmias. In some cases, activated charcoal may need to be administered.
- Alcohol, a powerful CNS depressant, is the most widely abused drug in the United States. A patient may be acutely intoxicated with alcohol or may be a chronic alcohol abuser. In either case, manage the ABCs and expect vomiting. A patient with DTs may be agitated or combative and needs reassurance.
- Opioids produce sleep or altered mental status; some opioids may produce euphoria. In the case of an opioid overdose, manage the ABCs, establish vascular access, administer naloxone as indicated, and call for paramedic backup for further medication administration and cardiac monitoring. In the case of a cardiac arrest from an opioid overdose, follow the American Heart Association algorithm for assessment and management.
- The main stimulants of concern for AEMTs include cocaine, amphetamines, methamphetamine, and synthetic cathinones. The classic presentation of stimulant overdose includes excitement, delirium, tachycardia, hypertension or hypotension with a fast pulse rate, and dilated pupils. Treatment is managing the ABCs, calling for paramedic backup to control anxiety and seizures and to administer benzodiazepines per local protocol, and providing reassurance.
- Treatment of the patient who has used marijuana or cannabis compounds focuses on supportive care, because there is little likelihood of a serious medical complication from marijuana use.
- A hallucinogen alters a person's sensory perception, causing the individual to see, hear, or feel things that are not actually present. Hallucinogenic substances include LSD, psilocybin mushrooms, phencyclidine, ketamine, and mescaline. Treat patients using hallucinogens by providing transport to the appropriate facility and psychological support.
- Sedative-hypnotic drugs may reduce anxiety and produce drowsiness and sleep. Barbiturates and benzodiazepines are the main drugs of concern in this category. Patients present much like patients with alcohol intoxication. Manage the ABCs, monitor for shock, and administer fluids if needed.
- Signs and symptoms of overdose with cardiac drugs vary, but may include hypotension,

weakness or confusion, nausea and vomiting, rhythm disturbances, headache, and difficulty breathing. As with all emergencies, ensure a patent airway, provide adequate ventilation, and administer high-flow supplemental oxygen.

- Other medications that may prompt calls related to overdose include erectile dysfunction medications, psychiatric medications (eg, TCAs, MAOIs, SSRIs, lithium), OTC pain-relief medications (eg, NSAIDs, salicylates, acetaminophen), and drugs used to facilitate sexual assault (eg, gamma-hydroxybutyrate). After administering the appropriate on-scene care (which may sometimes include activated charcoal), these patients should be transported to the appropriate facility.
- Cholinergic agents include organophosphates and nerve gases. These agents overstimulate normal body functions that are controlled by the parasympathetic nerves, resulting in salivation, mucus secretion, urination, lacrimation, and an abnormal heart rate. Patients must be decontaminated before initiating care.
- Carbon monoxide is a common cause of fatal poisoning. Signs and symptoms of CO poisoning vary and are vague, often resembling the onset of the flu. Remove the patient from the environment, administer 100% oxygen via nonrebreathing mask or bag-mask–assisted ventilations, and consider performing carbon monoxide monitoring.
- Lead poisoning is associated with a long list of signs and symptoms, with encephalopathy being a major cause of mortality and morbidity in these patients. The toxic effects of an iron exposure reflect the amount of elemental iron ingested. With both of these types of metal poisoning, AEMT should provide supportive care as there is little that can be done for these patients in the field.
- In case of chlorine gas poisoning, first remove patients from the area of exposure, then quickly triage the patients, prioritizing those with breathing problems. Irrigate burning or itching eyes with water, as well as any areas of the skin that have come in contact with the chlorine.
- Immediate treatment is required for cyanide poisoning. Administer 100% oxygen via non-rebreathing mask or bag-mask–assisted ventilations. Most patients who have swallowed caustic substances present with severe pain in the mouth, throat, or chest. Provide immediate transport to the ED. Establish vascular access en route. If the patient was exposed to a strong alkali, diluting and flushing away the caustic substance is the first priority.
- Some alcohols, including methyl alcohol and ethylene glycol, are even more toxic than ethyl alcohol (drinking alcohol). Immediate transport to the ED is essential when patients have ingested these substances.
- Treat patients who have inhaled hydrocarbons by removing the patient from the noxious environment, administering high-concentration supplemental oxygen, and providing prompt transport to the appropriate facility.
- Patients with food poisoning develop gastrointestinal complaints. Hypotension secondary to fluid loss and electrolyte imbalance becomes likely, and respiratory distress or arrest can occur. Treatment for patients with food poisoning is usually supportive.
- Most poisonous plant-related exposures involve children younger than 6 years. Plants may irritate the skin, affect the circulatory system, or cause abdominal complaints. Most plant-related exposures require no treatment. Consult a poison center and medical control per local protocol.

Vital Vocabulary

alcoholism A state of physical and psychological addiction to ethanol.

amphetamines A class of drugs that increase alertness and excitation (stimulants); includes methamphetamine (crank or ice),

methylenedioxymphetamine (MDA, Adam), and methylenedioxymethamphetamine (MDMA, Eve, Ecstasy).

antagonist Something that counteracts the action of something else; a drug of this type

has an affinity for a cell receptor and, when it binds to that receptor, the cell is prevented from responding.

barbiturates Any medications of a group of barbituric acid derivatives that act as central nervous system depressants and are used as sedatives or hypnotics; potent sedative-hypnotics historically used as sleep aids, as anti-anxiety drugs, and as part of the regimen for seizure control.

benzodiazepines Sedative-hypnotic drugs that provide muscle relaxation and mild sedation, commonly used to treat anxiety, seizures, and alcohol withdrawal; includes drugs such as diazepam (Valium) and midazolam (Versed).

carbon monoxide (CO) An odorless, highly poisonous gas that results from the incomplete oxidation of carbon during combustion.

caustics Chemicals that are acids or alkalis; they cause direct chemical injury to the tissues they contact.

chemical suicide A method of suicide that involves mixing certain household chemicals in an enclosed space to create toxic gases, such as hydrogen sulfide and hydrogen cyanide, as the chemicals combine; also called detergent suicide.

delirium tremens (DTs) A severe withdrawal syndrome seen in people with alcoholism who are deprived of ethyl alcohol, which is characterized by restlessness, fever, sweating, disorientation, agitation, and seizures; it can be fatal if untreated.

dieffenbachia A common houseplant that resembles “elephant ears”; its ingestion leads to burns of the mouth and tongue and, possibly, paralysis of the vocal cords and nausea and vomiting. In severe cases, ingestion may cause edema of the tongue and larynx, leading to airway compromise.

drug A substance that has some therapeutic effect (such as reducing inflammation, fighting bacteria, or producing euphoria) when given in the appropriate circumstances and in the appropriate dose.

drug abuse Any use of drugs that causes physical, psychological, economic, legal, or social

harm to the user or others affected by the user's behavior.

drug addiction A chronic disorder characterized by the compulsive use of a substance that results in physical, psychological, or social harm to the user who continues to use the substance despite the harm.

gamma-hydroxybutyrate (GHB) A sedative and central nervous system depressant.

habituation The situation in which there is a physical tolerance and psychological dependence on a drug or drugs.

hallucinogen An agent that produces false perceptions in any one of the five senses.

hydrocarbons Compounds made up of hydrogen and carbon atoms; they are frequently obtained from the distillation of petroleum.

illicit In relation to drugs, illegal drugs such as marijuana, cocaine, and lysergic acid diethylamide.

licit In relation to drugs, legalized drugs such as coffee, alcohol, and tobacco.

lithium The cornerstone drug for the treatment of bipolar disorder.

marijuana The dried leaves and flower buds of the *Cannabis sativa* plant, which are smoked to achieve a high.

methamphetamine A highly addictive drug in the amphetamine family.

monoamine oxidase inhibitors (MAOIs) Psychiatric medication used primarily to treat atypical depression by increasing norepinephrine and serotonin levels in the central nervous system.

opiate Any of the various alkaloids derived from the opium or poppy plant.

opioid A drug that acts as a central nervous system depressant and produces insensibility or stupor. An opioid can be a natural product derived from the opium or poppy plant or a synthetic product designed to produce similar effects.

organophosphates A class of chemicals found in many insecticides used in agriculture and in the home.

overdose Consumption of an excessive quantity of a drug that, when taken or administered, can have toxic or lethal consequences.

physical dependence A physiologic state of adaptation to a drug, usually characterized by tolerance to the drug's effects and a withdrawal syndrome if use of the drug is stopped, especially abruptly.

poison A substance whose chemical action could damage structures or impair function when it is introduced into the body.

potentiation Enhancement of the action of a drug by the administration of another drug.

psychological dependence The emotional state of craving a drug to maintain a feeling of well-being.

salicylates Aspirin-like drugs.

sedative-hypnotic A drug used to reduce anxiety, calm agitated patients, and help produce drowsiness and sleep; a central nervous system depressant.

selective serotonin reuptake inhibitors (SSRIs) A class of antidepressants that inhibit the reuptake of serotonin.

spice An illicit drug consisting of a blend of synthetic cannabinoids; it can produce short- and long-term psychotic effects.

stimulants Medications or chemicals that temporarily enhance central nervous system and sympathetic nervous system functioning and produce an excited state.

synergism The action of two substances such as drugs, in which the total effects are greater than the sum of the independent effects of the two substances.

tolerance Physiologic adaptation to the effects of a drug, such that increasingly larger doses of the drug are required to achieve the same effect.

toxicologic emergencies Medical emergencies caused by toxic agents such as poisons.

toxicology The study of toxic or poisonous substances.

toxidrome The syndromelike symptoms of a poisonous agent.

toxin A poison or harmful substance produced by bacteria, animals, or plants.

tricyclic antidepressants (TCAs) A group of drugs used to treat severe depression and manage pain; even minimal dosing errors with these agents can cause toxic results.

withdrawal syndrome A predictable set of signs and symptoms, usually involving altered central nervous system activity, that occurs after the abrupt cessation of a drug or after rapidly decreasing the usual dosage of a drug.

Chapter 24

Psychiatric Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Psychiatric

Recognition of

- Behaviors that pose a risk to the AEMT, patient, or others (pp 1180–1184)

Assessment and management of

- Basic principles of the mental health system (p 1182)
- Acute psychosis (pp 1194–1196)
- Suicidal/risk (pp 1196–1197)
- Agitated delirium (pp 1197–1198)

KNOWLEDGE OBJECTIVES

1. Discuss the potential causes of behavioral emergencies, including organic and functional causes. (pp 1182–1185)
2. Identify psychiatric signs and symptoms. (pp 1185–1186)
3. Describe the assessment process for patients with psychiatric emergencies, including safety guidelines and specific questions to ask. (pp 1186–1189)
4. Discuss risk factors that help indicate whether a patient may become violent. (p 1189)
5. Discuss the importance of history taking when assessing a patient with a psychiatric emergency. (pp 1189–1191)
6. Discuss general management of a patient with a psychiatric emergency. (pp 1191–1192)
7. Explain the safe management of a potentially violent patient. (pp 1192–1193)
8. Discuss assessment and management of specific psychiatric emergencies. (pp 1194–1196)
9. Describe the care for a patient experiencing a psychotic episode. (pp 1193–1194)
10. Explain how to recognize the behavior of a patient at risk of suicide, and discuss the management of such a patient. (pp 1196–1197)
11. Define agitated delirium and describe the care for a patient with agitated delirium. (pp 1197–1198)
12. Discuss types of mood disorders and their management, including mania and depression. (pp 1198–1200)
13. Discuss types of neurotic disorders and their management, including generalized anxiety disorder, phobias, and panic disorder. (pp 1200–1202)
14. Discuss medicolegal considerations and their relevance in psychiatric emergencies. (pp 1202–1203)
15. Describe situations where restraint may be justified. (pp 1203–1205)
16. Describe methods used to restrain patients. (p 1204)

17. Explain the causes of posttraumatic stress disorder (PTSD), along with its signs and symptoms. (pp 1205–1206)

18. Describe the special needs of combat veterans and their management. (p 1206)

SKILLS OBJECTIVE

1. Demonstrate the techniques used to mechanically restrain a patient. (pp 1203–1205)

Introduction

As an advanced emergency medical technician (AEMT), you can expect to be called on to care for patients who are experiencing a psychological or behavioral crisis. This kind of crisis may be caused by a medical condition, a mental illness, use of mind-altering substances, stress, or many other reasons. This chapter discusses various kinds of behavioral emergencies, including those involving overdoses, violent behavior, and mental illness. You will learn how to assess a person who exhibits signs and symptoms of a behavioral emergency and how to determine the kind of emergency care that may be required in these situations. The chapter also covers legal concerns when caring for patients who are disturbed. Finally, it describes how to identify and manage the potentially violent patient, including the use of restraints.

Myth and Reality

Everyone experiences an emotional crisis at some point in life, some more severe than others. Even perfectly healthy people may have some of the signs and symptoms of mental illness from time to time. Therefore, you should not assume that you have a mental illness when you behave in certain ways that are discussed in this chapter. With that caveat in mind, you should also avoid making the same assumption about a patient in any given situation.

A common misconception about mental illness is that if you are feeling “bad” or “depressed,” you must be “sick.” That is simply untrue. There are many justifiable reasons for feeling depressed, including divorce, loss of a job, and the death of a relative or friend. For example, a teenager who just broke up with his girlfriend of 12 months may temporarily withdraw from ordinary activities and feel sad. This is a normal reaction to a crisis. However, a person whose Monday morning blues are lasting

until Friday, week after week, may have a behavioral problem.

Many people believe that all people with mental health disorders are dangerous, violent, or otherwise unmanageable; this is also untrue. Only a small percentage of people with mental health problems fall into these categories. However, as an AEMT, you may be exposed to a higher proportion of violent patients because dealing with them is part of your job. You are seeing people who are, by definition, considered to be having an emergency; otherwise, your assistance would not have been requested. You are there because family members or friends felt unable to manage the patient by themselves. The situation could be a result of the use or abuse of drugs or alcohol. Alternatively, your assistance may have been requested because the patient has a long history of mental illness and is reacting to a particularly stressful event.

Whereas you cannot determine what has caused a person's behavioral problem, you may be able to predict when a person will become violent. The ability to predict violence is an important assessment tool for the AEMT.

Defining Behavioral Emergencies

Behavior is what you can see of a person's response to the environment—that is, the person's actions. Sometimes, it is obvious what a person is responding to. For example, a person who is punched may respond by running away, bursting into tears, or hitting back. Sometimes, the source of distress is less clear, such as when someone is depressed for complex reasons.

Most of the time, people respond to the environment in reasonable ways. Over the years, they have learned to adapt to a variety of situations in daily life, including various stressors. This process

is called adjustment. At other times, however, the stress is so great that the normal methods of adjusting do not work. When this happens, a person's behavior is likely to change, even if only temporarily. This new behavior may not be appropriate or normal.

Regarding the concept of normal behavior, there exists some disagreement over what is “normal.” There is no clear idea or ideal model. The idea of what is normal tends to vary by cultural or ethnic group. Normal behavior is basically classified as whatever behavior society accepts. In contrast, abnormal or maladaptive behavior is anything that deviates from society's norms and expectations. It tends to interfere with the person's well-being and ability to function. It may also be harmful to an individual or group.

The definition of a **behavioral crisis** or emergency is any reaction to events that interferes with **activities of daily living (ADLs)** or has become unacceptable to the patient, family, or community. For example, when a person experiences an interruption in daily routine, such as washing, dressing, and eating, it is likely that the individual's behavior has become a problem. For that person, at that time, a behavioral emergency may exist. If the interruption of the daily routine tends to recur on a regular basis, the behavior is now also considered a *mental health* problem. It is now a pattern, rather than an isolated incident.

For example, a person who experiences a panic attack after having a heart attack is not necessarily mentally ill. Likewise, you would expect a person who is fired from a job to have some type of reaction, often sadness and depression. These behavioral problems are short-term and isolated events. However, the person who reacts with a fit of rage, attacking people and property or going on a drinking

or drug spree for a week, has gone beyond what society considers appropriate or normal behavior. This person is clearly undergoing a behavioral emergency. Usually, if an abnormal or disturbing pattern of behavior lasts for at least a month, it is regarded as a matter of concern from a mental health standpoint. For example, chronic **depression** is a medical diagnosis of a persistent feeling of sadness, despair, and discouragement. This type of long-term problem would be considered a mental health disorder.

A person who is no longer able to respond appropriately to the environment may be having what is called a psychological or psychiatric emergency. When a psychiatric emergency arises, patients may show agitation or violence or become a threat to themselves or to others. This situation is more serious than a more typical behavioral emergency that causes inappropriate behavior such as interference with ADL or intolerable actions. An immediate threat to the person involved or to others in the immediate area, including family, friends, bystanders, and emergency responders (including AEMTs),

Words of Wisdom

The medicolegal issues associated with responses to behavioral emergencies put added emphasis on thorough and specific documentation of the call. Record detailed, objective findings that support the conclusion of abnormal behavior (eg, withdrawn, will not talk, crying uncontrollably) and quote the patient's own words when appropriate (eg, “Life isn't worth living anymore” or “The voices are telling me to kill people”). Avoid subjective, judgmental statements, because they create the impression that you based your care on personal bias rather than the patient's needs.

YOU are the Provider

Part 1

You are dispatched to a 70-year-old man who is complaining of chest pain. Law enforcement has also been dispatched to the scene. The patient is well-known and has a history of posttraumatic stress disorder (PTSD). He has been violent with responders in the past and has a tendency to hallucinate and have flashbacks after having served in Vietnam.

1. Does this scene need to be treated differently than other scenes just because the patient has a mental illness?
2. Who has overall control of this scene, emergency medical services (EMS) or law enforcement?

should be considered a psychiatric emergency. For example, a person might respond to the death of a spouse by attempting suicide. However, not all major life disruptions necessarily involve violent behavior or harm to an individual. Disruption can take many forms; not all include violence, nor are they all psychiatric emergencies.

The Magnitude of Mental Health Problems

According to the National Institute of Mental Health, at one time or another, nearly one in five Americans has some type of **mental disorder**, an illness with psychological or behavioral symptoms that may result in impaired functioning.¹ Such a mental disorder can be caused by a social, psychological, genetic, physical, chemical, or biologic disturbance. Common causes of behavioral alterations are listed in **TABLE 24-1**.

Pathophysiology of Abnormal Behavior

Although sudden grief, emotional conflicts, and other psychological problems can cause behavioral

emergencies, sudden illness, recent trauma, drug or alcohol intoxication, and diseases of the brain, such as Alzheimer disease, can produce abnormal behavior as well. Likewise, altered mental status can arise from hypoglycemia, hypoxia, and exposure to excessive heat or cold. Behavioral emergencies constitute serious mental health problems and incapacitate more people than all other health problems combined.² As an AEMT, you are not responsible for diagnosing the underlying cause of a behavioral or psychiatric emergency. However, you should know the two basic categories of diagnosis a physician will use: organic (physical) and functional (psychological).

Organic Causes of Behavioral Emergencies

Organic brain syndrome is a temporary or permanent dysfunction of the brain caused by a disturbance in the physical or physiologic functioning of brain tissue. It is a type of neurocognitive disorder, which is a general term that describes decreased mental function caused by a medical disease other than a psychiatric illness. Causes of organic brain syndrome include sudden illness; recent trauma to the head; seizure disorders; drug and alcohol intoxication, overdose, or withdrawal; and diseases of the brain, such as Alzheimer disease and meningitis.

Altered mental status can arise from a low blood glucose level, lack of oxygen, inadequate blood flow to the brain, and excessive heat or cold. An altered mental status, or a change in the way a person thinks or behaves, may be one indicator of a psychiatric disease such as bipolar disorder. A patient displaying bizarre behavior may actually have an acute medical illness that is the cause, or a partial cause, of the behavior. Recognizing this possibility may allow you to save a life.

Environmental Causes

A person's environment exerts a tremendous influence on behavior. Typically, that environment includes both psychosocial and sociocultural influences on behavior.

When people are consistently exposed to stressful psychosocial events (eg, childhood trauma) or developmental influences (eg, parents who deprived them of love, care, support,

TABLE 24-1 Common Causes of Behavioral Alterations
Hypoglycemia
Hypoxia
Hypoperfusion
Head trauma
Mind-altering substances
Psychogenic—resulting in psychotic thinking, depression, or panic
Environmental exposure (excessive cold, excessive heat)
Meningitis
Seizure disorders
Toxic ingestions/overdose
Withdrawal from drugs or alcohol

and encouragement), they may develop abnormal reactions. When a person's basic needs are threatened, that individual faces a crisis. A person in crisis has two alternatives for dealing with this threat: (1) cope with it by finding ways to alter the situation or the individual's perception of it so that the threat is no longer so stressful, or (2) attempt to alleviate the discomfort by escaping from the stress. Escape may take many forms, including use

of alcohol and drugs, psychiatric symptoms, and even suicide.

Humans are social beings, preferring to live in groups. Not surprisingly, then, sociocultural factors directly affect biology, behavior, and responses to the stress of emergencies. For example, the effects of assault, rape, racial attacks, or the death of a loved one may produce significant changes in a person's behavior.

Special Populations

As the population ages, you will begin to see more geriatric patients. In responding to an increasing number of patients older than 65 years, you will probably notice some behavioral or mental health problems, including depression, dementia, and delirium. These mental status changes can affect your ability to thoroughly assess and treat the ill or injured geriatric patient. Understanding the causes of altered behavior in an older patient will help you provide better patient care.

Depression is one of the more common mental status problems that you will see in the older population. Whereas much attention has been given to depression in younger adults, the media have not given as much coverage to older adults' mental health challenges. As an AEMT, you can recognize a problem and perhaps suggest resources that may improve the person's day-to-day quality of living or prevent suicide in the depressed older person.

Depression has many causes: some organic, some psychological, and some cultural. Organic causes of depression may include an emotional response to a major illness such as cancer or dementia. In addition, some medications can induce a feeling of depression, especially if they interact with other prescription or over-the-counter drugs. Changes in the endocrine system, such as menopause, can elicit depression. Psychological causes of depression include dealing with the effects of getting older; older adults could feel that life has passed them by, leading to depression. Some cultural attitudes may also cause stress for the older person: whereas some cultures revere their elders, others tend to view them as a burden, causing anguish and feelings of uselessness in older adults.

Given the many possible causes of depression, an older adult can feel helpless and hopeless. Some people with depression can be argumentative; others can be placid. Some patients with depression may trivialize complaints, not wanting to be a bother to anyone. Someone who sees no way out of a situation may turn

to suicide. You should be alert for suicidal gestures and ideation, even though the signs may not be obvious.

Whereas depression can create behavioral problems in older patients, dementia is another cause of abnormal behavior. The most common cause of dementia is primary progressive dementia, also known as Alzheimer dementia. According to the Alzheimer's Association, an estimated 5.8 million Americans are living with Alzheimer disease as of 2020. That number is expected to be nearly 14 million by 2050. Alzheimer disease is the sixth leading cause of death in the United States, with one in three people older than 65 years dying with Alzheimer disease or another form of dementia.⁴ Currently, there is no cure for Alzheimer disease, but several prescription medications have been introduced that may reduce the symptoms of Alzheimer disease, such as memory loss, or may help slow the progression of the disease.

During the progression of Alzheimer disease, the patient may exhibit openly hostile behavior and may kick, yell at, pinch, and hit you, your partner, or the caregiver. You might need to restrain the violent patient, but do so gently and only to the point at which the violent behavior stops.

Other causes of altered behavior may include diabetic emergencies, heat- and cold-related illnesses, poisoning, overdose, strokes and transient ischemic attacks, and infection. It is interesting to note that a urinary tract infection or constipation can alter an older person's behavior; however, the mechanism by which this behavior change evolves is not fully understood.

When you respond to a call for help, you should accept the possibility of depression and other potential mental health problems in the older patient. Do not discount or devalue the patient's feelings or emotions. Be alert for suicide gestures, and pay attention to any statements the patient may make about death. To obtain the patient's cooperation, you can elicit their help in providing care for the acute illness or injury. A smile and a touch can go a long way toward alleviating fear in many of your patients, especially older patients.

Injury and Illness as Causes

Acute illness can overwhelm a person, causing changes in behavior. Medical problems such as severe infections, electrolyte abnormalities, and many types of metabolic disorders result in stress on coping mechanisms and can cause abnormal behaviors.

The number of traumatic events occurring in the general population has increased in both frequency and intensity in recent years. An acute traumatic situation creates a great deal of stress for the person experiencing the trauma as well as those around the individual. As an AEMT, you are not immune to this stress. **Posttraumatic stress disorder (PTSD)** is a severe form of anxiety that stems from a traumatic experience; it is characterized by the individual reliving the stress of the original situation. Causes of PTSD can range from combat military

service and terrorist attacks to a car crash or sexual assault.

Substance-Related Causes

Substance-related mental disorders may stem from the use of alcohol, cigarettes, illicit drugs, and other substances that change the way a person feels, behaves, or thinks. These disorders cost thousands of lives and billions of dollars annually. It was not until the late 20th century that substance-related disorders were recognized as a complex biologic and psychological problem rather than a sign of moral weakness. Currently, an estimated 7.9 million adults in the United States have both a substance use disorder and a mental disorder.³

Functional Disorders

A **functional disorder** is one in which the etiology cannot be traced to an obvious change in the actual structure or physiology of the brain itself. Something has gone wrong, but the root cause cannot be identified definitively as brain dysfunction. Schizophrenia, anxiety conditions, and depression are good examples of mental disorders. There may be a chemical or physical cause for these disorders, but it is not always obvious or well understood.

Words of Wisdom

You should know the two basic types of underlying causes of behavioral emergencies: organic (physical) and functional (psychological).

YOU are the Provider

Part 2

The patient is sitting in a recliner in the living room and appears to have just finished lunch. There is an empty plate with a fork and knife next to his chair. He is mumbling to himself, but acknowledges your presence and does not appear to be aggressive. The patient reluctantly agrees to allow you to perform a physical examination. He states his chest feels “full,” but it does not hurt and he has not had any difficulty breathing.

Recording Time: 1 Minute

Appearance	Anxious, agitated
Level of consciousness	Alert and oriented to person, place, time, and event; however, experiencing auditory hallucinations
Airway	Patent
Breathing	Normal rate and rhythm
Circulation	Strong radial pulses; skin warm, dry, and pink

3. This patient has a known history of mental illness. Does he need to be transported to the hospital?
4. Does this patient require an ambulance transport to the emergency department, or should law enforcement transport him?

Words of Wisdom

A patient displaying bizarre behavior may actually have an acute medical illness that is the cause, or a partial cause, of their behavior. Behavioral changes may occur as a result of medical conditions such as diabetes or stroke, or may be the result of head injury or drug and/or alcohol intoxication. Other conditions presenting as psychological disorders must be identified and promptly treated.

Psychiatric Signs and Symptoms

When a person's physical health is challenged, the human body mobilizes various defenses to correct the abnormality. The patient experiences the effects of those abnormalities and corrective measures as symptoms, and you observe them as signs. Physical symptoms and signs reflect the body's attempts to

maintain its balance in the face of physical stress. When a person's mental health is challenged, similar psychological mechanisms or behaviors are mobilized to help return the person's mental state to homeostasis. These defensive mechanisms present as various types of psychiatric signs and symptoms or behaviors that you may also observe.

Like the symptoms and signs of physical illness, psychiatric symptoms and signs can be grouped according to the "systems" they affect. Here, however, the focus is on systems of psychological (rather than physiologic) functioning. The psychological functions involved are consciousness, motor activity, speech, thought, affect, memory, orientation, and perception. Psychiatric signs and symptoms can affect the following areas: consciousness, motor activity, speech, thinking, mood and affect, memory, orientation, perception, and intelligence. The signs and symptoms of these disorders are listed in **TABLE 24-2**.

TABLE 24-2 Classification of Psychiatric Signs and Symptoms

Function Affected	Psychiatric Signs and Symptoms
Consciousness	Distractibility and inattention Confusion Delirium Stupor and coma
Motor activity	Restlessness Stereotyped movements (repetition of movements that do not seem to serve any useful purpose) Compulsions (repetitive actions that are carried out to relieve the anxiety of obsessive thoughts) Slow movements
Speech	Slow speech Acceleration or pressure of speech (the pouring out of words like water escaping under pressure) Neologisms (words the patient invents) Echolalia (the patient echoes words heard) Mutism (the patient does not speak at all)
Thought progression	Flight of ideas (accelerated thinking in which the mind skips very rapidly from one thought to the next) Slowness of thought Perseveration (repetition of the same idea over and over again) Circumstantial thinking (the inclusion of many irrelevant details)
Thought content	Delusions (false beliefs) Obsessions Phobias (obsessive, irrational fears of specific things or situations, such as fear of heights, fear of open places, fear of confined spaces, or fear of certain animals)

(continues)

TABLE 24-2 Classification of Psychiatric Signs and Symptoms (*continued*)

Function Affected	Psychiatric Signs and Symptoms
Mood and affect	Anxiety Euphoria Depression Inappropriate affect (emotion that is out of synch with the situation—for example, wearing a smile while discussing a parent's death) Flat affect (the absence of emotion; appearing to feel no emotion at all)
Memory	Amnesia Confabulation (inventing experiences to fill gaps in memory)
Orientation	Disoriented to person, place, and time
Perception	Illusions Hallucinations
Intelligence	Difficulty learning

Patient Assessment

Scene Size-up

When evaluating a situation that is considered a behavioral emergency, you should first consider your safety and then determine how the patient is responding to the environment. Is the situation unduly dangerous to you and your partner? Do you need immediate law enforcement backup? Does the patient's behavior seem typical or normal given the circumstances? For example, a patient who has just been assaulted has good reason to be fearful of other people, including you. Conversely, if you ask, "Do you know where you are?" and the person replies, "The planet Venus" (and does not seem to be joking), you may conclude that the person is disoriented, regardless of the cause.

Assessment of the environment can help give clues to the patient's condition or the cause of the emergency. Is the home too hot or too cold? Is the home well-kept and secure? Are there hazardous conditions? Look for potential clues from the patient's social history; general living conditions; availability of social and family support; activity level; medications; overall appearance with respect to nutrition, general health, cleanliness, and personal hygiene; and attitude and mental well-being.

All the regular AEMT skills—assessment, providing care, patient approach, history taking, and patient communication—are used in behavioral emergencies. With behavioral emergencies, you should recognize that patient assessment is also part of the treatment. As soon as you speak to the patient, your voice and manner will affect the patient's condition, for better or worse.

In addition, some other management techniques may be necessary. It is beyond the scope of this chapter to discuss all of these techniques, but you should follow general guidelines to ensure your safety at the scene of a behavioral emergency (**TABLE 24-3**).

Determine the mechanism of injury and/or nature of illness. For example, a patient with diabetes may have an altered mental status because of a low blood glucose level.

Primary Survey

As you approach the patient, respect the patient's territory and limit physical touching without permission. Approach slowly and purposefully while avoiding threatening actions, statements, and questions. Assess the patient's pupils carefully, because they may indicate other causes of altered mental status. For example, constricted pupils may indicate opiate ingestion, or unequal pupils may

TABLE 24-3 Safety Guidelines for Behavioral Emergencies

Assess the scene. If the patient is armed or has possession of potentially harmful objects, ensure that these objects have been removed by law enforcement personnel before you provide care.

Be prepared to spend extra time. It may take longer to assess, listen to, and prepare the patient for transport.

Have a definitive plan of action. Decide who will do what. If restraint is needed, how will it be accomplished?

Identify yourself calmly. Try to gain the patient's confidence. If you begin shouting, the patient is likely to shout louder or become more excited. A low, calm voice is often a quieting influence.

Be direct. State your intentions and what you expect of the patient.

Stay with the patient. *Do not let the patient leave the area, and do not leave the area yourself unless law enforcement personnel can and will stay with the patient.* Otherwise, the patient may go to another room and obtain weapons, retreat to the bathroom and lock the door, or take pills.

Encourage purposeful movement. Help the patient get dressed and gather appropriate belongings to take to the hospital.

Express interest in the patient's story. Let the patient tell you what happened or what is going on now in their own words. However, do not play along with auditory or visual disturbances.

Keep a safe distance from the patient. Everyone needs personal space. Furthermore, you want to be sure you can move quickly if the patient becomes violent or tries to run away. Do not physically talk down to or directly confront the patient. A squatting, 45° angle approach is usually not confrontational; however, it may hinder your movements. Do not allow the patient to get between you and the exit.

Avoid fighting with the patient. You do not want to get into a power struggle. Remember, the patient is not responding to you in a normal manner; the patient may be wrestling with internal forces over which neither of you has control. You and others may be stimulating these inner forces without knowing it. If you can respond with understanding to the feeling that the patient is expressing, whether this is anger, fear, or desperation, you may be able to gain the patient's cooperation. If it is necessary to use force, ensure that you have adequate help and move toward the patient quietly and with assured firmness.

Be honest and reassuring. If the patient asks whether they have to go to the hospital, the answer should be, "Yes, that is where you can receive medical help."

Do not judge. You may see behavior that you dislike. Set those feelings aside, and concentrate on providing emergency medical care.

© Jones & Bartlett Learning.

indicate cerebral trauma. Form a general impression of your patient (TABLE 24-4).

A behavioral crisis puts tremendous stress on a person's coping mechanisms, including natural abilities and training. The person is incapable of responding reasonably to the demands of the environment. This state may be temporary, as in an acute illness, or longer-lived, as in a complex, chronic mental illness. In either situation, the patient's perception of reality may be compromised or distorted.

When performing your assessment, it is important to limit the number of people around the patient. Remember to stay alert to potential danger.

A patient in unstable condition may become violent at any time. Watch for signs of agitation or aggression. It is important to separate the patient from bystanders or family members who seem to be exacerbating the patient's condition. You may ask them to step into another room and speak to your partner, or you may take the patient to the ambulance before beginning your primary survey, if appropriate.

Violent patients make up only a small percentage of those experiencing a behavioral or psychiatric crisis. Nevertheless, the potential for violence by such a patient should always be an important consideration for you. Although a patient with a large

TABLE 24-4 Evaluating a Behavioral Crisis**General**

How is the patient dressed? Is the dress appropriate for the time of year and occasion? Are the clothes clean or dirty?

Has the patient committed self-harm? Is there damage to the surroundings?

Speech

How does the patient respond to you?

- How does the patient feel?
- Is there trauma involved?
- Is there a medical problem?

Does the patient answer your questions appropriately?

Are the patient's vocabulary and expressions what you would expect under the circumstances? Are they in line with the patient's social and educational background?

Is the patient alert and able to speak logically and coherently?

Skin

What is the quality of the patient's skin?

- Color?
- Temperature?
- Condition?

Posture/Gait

Are the patient's movements coordinated or jerky and awkward? Does the patient appear to be agitated?

Are the patient's movements purposeful? Are the movements helping to accomplish a task, such as sitting down and putting on a pair of shoes, or do they appear to be aimless, such as rocking back and forth in the chair?

Does the patient appear relaxed or stiff and guarded?

Mental Status

Does the patient understand why you are there?

Mood

Is the patient withdrawn or detached?

Is the patient hostile or friendly? Too friendly?

What are the patient's facial expressions? Are they bland and flat or expressive? Does the patient show joy, fear, or anger as appropriate? To what degree?

What is the patient's mood? Does the patient seem agitated, elated, or abnormally depressed?

Does the patient appear fearful or worried?

Thought

Does the patient express disordered thoughts, delusions, or hallucinations? Does the patient appear to be seeing, hearing, or responding to people or situations that are not evident to you?

Perception

Are the patient's responses to events and the environment appropriate?

Judgment

Does the patient exhibit rational judgment?

Memory

Is the patient's memory intact? Check orientation to time, place, and person by asking the patient the following questions:

- Do you know what day/month/year it is?
- Do you know where you are?
- Do you know who I am?

Attention

Is the patient easily distracted? Is the patient able to concentrate?

© Jones & Bartlett Learning.

body size may be intimidating, there is no correlation between the size of the patient and the potential for violence.

Consider the following risk factors when assessing the level of danger:

- **History.** Has the patient previously exhibited hostile, overly aggressive, or violent behavior? Ask people at the scene, or request this information from law enforcement personnel or family.
- **Posture.** How is the patient sitting or standing? Is the patient tense, rigid, or sitting on the edge of their seat? Such physical tension is often a warning signal of impending hostility.
- **The scene.** Is the patient holding or near potentially lethal objects such as a knife, gun, glass, scissors, or bat (or near a window or glass door)? Also take note of conventional household objects that the patient could use as weapons, such as lamps, heavy dishes, hand tools, or figurines.
- **Vocal activity.** Which kind of speech is the patient using? Loud, obscene, erratic, and bizarre speech patterns usually indicate emotional distress. Someone using quiet, ordered speech is not as likely to strike out as someone who is yelling and screaming. However, do not discount the possibility of violent behavior in the quiet patient.
- **Physical activity.** The motor activity of a person experiencing a psychiatric crisis may be the most telling factor of all. The patient who has tense muscles, clenched fists, glaring eyes,

or is pacing, cannot sit still, or is fiercely protecting personal space requires careful watching. Agitation may predict a quick escalation to violence.

Other factors to consider in assessing a patient's potential for violence include the following:

- Poor impulse control
- A history of truancy, fighting, and uncontrollable temper
- Low socioeconomic status, unstable family structure, or inability to keep a steady job (note, however, that violence occurs among all classes and that socioeconomic class is a relative concept, depending on geographic areas)
- Tattoos, especially those with gang identification or statements such as "Born to Kill" or "Born to Lose," or jail-related tattoos (jail-related tattoos tend to be homemade and located on the hands or forearms)
- Substance abuse
- Depression (Depression is associated with a threefold increased risk of violence compared to the general population.⁵)
- Functional disorder (If the patient says that voices are telling them to kill, believe it.)

As with any patient, determine the presence of any life-threatening medical conditions by performing an assessment of the patient's ABCDEs (Airway, Breathing, Circulation, Disability, and Exposure). Assess the airway to make sure it is patent and adequate. Next, evaluate the patient's breathing. Provide any appropriate interventions on the basis

of your assessment findings. You will need to assess the pulse rate, quality, and rhythm. Obtain the systolic and diastolic blood pressures when possible. Assessing a patient's circulation includes an evaluation for the presence of shock and bleeding. Assess the patient's perfusion level by evaluating skin color, temperature, and condition.

While you are assessing the patient's mental status, note any evidence of rage, elation, hostility, depression, fear, anger, anxiety, confusion, or any other abnormal behavior. Observe for any signs of overt behavior and give close attention to body language, such as abnormal posture or threatening gestures. Talk to the patient as you continue your assessment, and explain all procedures that you intend to perform.

Unless the patient's condition is unstable from a medical problem or trauma, prepare to spend time at the scene with the patient. Depending on your local protocol, there may be a specific facility to which patients with mental problems are transported.

Safety

When you are assessing a patient who is experiencing a behavioral emergency, it can be useful to obtain information separately from a relative or caregiver. Obtaining the patient's history in this way often yields valuable information and can help reduce the potential for violence when there is tension between the people involved.

History Taking

Once any life-threatening emergencies have been addressed, remove the patient from the crisis or disturbing situation. You should focus your questions during the history taking on the immediate problem to avoid confusion. Establishing a good rapport with the patient will enable you to provide better care. Use therapeutic interviewing techniques by engaging in active listening, being supportive and empathetic, limiting interruptions, and respecting the patient's personal space. Limit physical contact to minimize patient apprehension. Avoid using any threatening actions, statements, or questions. Approach the patient slowly and purposefully.

When you are talking with the patient, it is important to evaluate the potential for suicide or harm to others. Factors that increase these risks include recent depression, recent loss of a family member or friend, financial setback, drug use, or evidence of a detailed plan. If you are able to determine that the patient has actually established a plan for suicide or violence, there is a great risk of the patient carrying it out. Specifically, a patient who has a very detailed plan and access to the means to complete it is all the more likely to carry out the plan. For example, a patient who actually has a bottle of pills is much more likely to overdose than one who does not have ready access to pills.

Reflective listening, also called active listening, is a technique frequently used by mental health professionals to gain insight into a patient's thinking. It involves repeating back to patients what they have said, encouraging them to expand on their thoughts. Although it often requires more time to be effective than is available in an EMS setting, it may be a helpful tool for you to use when other communication techniques are unsuccessful. It is important to actively listen and to be supportive and empathetic. Allow time for the patient to answer and limit interruptions.

Sometimes a patient experiencing a behavioral or psychiatric emergency will not respond to any of your questions. In those situations, you may be able to determine much about the patient's emotional state from facial expressions, pulse rate, and respirations. Take note of the presence of tears, sweating, and blushing—these findings may be significant indicators of the patient's state of mind. Also, make sure you look at the patient's eyes; a patient who has a blank gaze or rapidly moving eyes may be experiencing central nervous system depression or some type of extra stress (**FIGURE 24-1**).

Family, friends, and observers may also be of great help in answering patient history questions. Together with your observations and interaction

Street Smarts

In many patients with autism or autism spectrum disorder, making eye contact can be very stressful for the patient and may cause agitation. Do not force eye contact.

FIGURE 24-1 Looking at the patient's eyes can provide useful clues about the individual's emotional state.

Courtesy of Rhonda Hunt.

with the patient, they should provide enough data for you to assess the situation. This part of the patient assessment has two primary goals: recognizing major threats to life and reducing the stress of the situation as much as possible.

When trying to determine the etiology of the patient's condition, you should consider five major areas as possible contributors:

- Is the patient's central nervous system functioning properly? For example, the patient may be experiencing diabetic problems, particularly hypoglycemia. The patient may have been poisoned or may be responding to physical trauma. Any of these situations could cause the patient to behave in an unusual or irrational manner.
- What is the general condition of the patient's environment? Is the patient dressed appropriately? Clean?
- Is there any evidence of substance abuse? Are hallucinogens or other drugs or alcohol a factor? Does the patient see strange things? Is everything distorted? Do you smell alcohol on the patient's breath?
- Are **psychogenic** circumstances, symptoms, or illness (caused by mental rather than physical factors) involved? These might include the death of a loved one, severe depression, a history of mental illness, threats of suicide, or some other major interruption of ADLs.
- If the patient has a history of psychiatric illness, has there been a recent change in medications? Often, treatment of functional

psychiatric illness is a trial-and-error process with medications and therapy. Doctors and therapists work with the patient and family to find the most effective course of treatment, with medication changes sometimes causing unexpected or undesirable outcomes. Also consider that some patients may refuse to take their medications.

Be sure to note any physical assessment findings or complaints of physical symptoms. Document the intellectual function: Is the patient oriented? Is the patient's memory intact? Is the patient able to concentrate and use the appropriate judgment? Does the patient have disordered thoughts, delusions, hallucinations, or unusual worries or fears, or express suicidal or homicidal threats? Also note the speech pattern and content. Is the speech garbled or unintelligible? What is the patient's mood like? What about appearance and hygiene? Finally, is the patient's motor activity normal? Be sure to accurately document all findings.

Special Populations

Although not all elderly patients have Alzheimer disease or dementia, consider these conditions as possible causes of abnormal behavior. In patients with any sort of dementia, it is essential to obtain information from relatives, friends, or extended-care facility staff. Facility staff such as certified nurse's aides may be a particularly useful resource for this information because they spend a significant amount of time interacting directly with their patients. Determining the patient's baseline mental status will be essential in guiding your treatment and transport decisions. However, it is important to remember that any patient with an altered mental status, regardless of history, should receive a complete assessment, including a check for hypoxia and hypoglycemia.

Secondary Assessment

Whereas much of your assessment involves interviewing the patient about any psychiatric history, you must also look for signs of an organic cause of the patient's behavior:

- Obtain the vital signs to look for signs of fever or indications of increased intracranial pressure.

- Examine the skin temperature and moisture, and note any prominent tattoos. Certain tattoos may suggest a tendency toward violence. Scars may indicate self-mutilation.
- Inspect the head for evidence of trauma.
- Check the pupils for size, equality, and reaction to light. Pupillary abnormalities may indicate a toxic ingestion or an intracranial process as the source of the patient's behavior.
- Note any unusual odors on the patient's breath such as poisons, alcohol, or ketones from diabetic ketoacidosis.
- Examine the extremities, looking for needle track marks, tremors, and unilateral weakness or loss of sensation.

Assessment Pearls

- Establish a baseline mental status for the patient to determine how this episode is different from normal.
- Immediately assess oxygen and glucose levels for any patient with an altered mental status.
- Consider the speed of onset of the incident. A sudden change in mental status is most likely the result of a medical condition such as hypoglycemia or hypoxia.
- Never leave a patient alone who is experiencing a behavioral emergency.
- Question the patient and/or family about possible traumatic events over the past week or so. Remember that a subdural bleed develops slowly and may be the result of a fall several days prior.
- Ask the patient or family about medication compliance.
- Examine medication bottles, paying particular attention to date filled, initial quantity, and remaining quantity.
- Do not encourage hallucinations. If the patient describes seeing something, calmly respond, "I understand that you are seeing _____. However, I/we do not see it."
- Encourage purposeful movement. Help the patient gather items such as shoes, a jacket, and medications.
- When assessing a combat veteran or a patient with a history of PTSD, avoid loud noises and sudden movements that may trigger an episode. Keep in mind that a car backfiring sounds like gunfire to those who have experienced active combat.

Unless a significant traumatic problem exists, a secondary assessment may be conducted to provide helpful information. Alternatively, on the basis of your transport time and the patient's mental status, the secondary assessment may be deferred.

Obtain vital signs when doing so will not exacerbate the patient's emotional distress. Make every effort to assess blood pressure, pulse, respirations, skin, and pupils. Remember that a behavioral crisis can be caused or precipitated by physiologic problems, such as a head injury or diabetic disorder, and that such a crisis can aggravate preexisting conditions. Do not forget that the physical person and the emotional person are one.

When it will not exacerbate the patient's emotional distress, you may use monitoring devices to measure and assess the patient's oxygenation and circulatory status. It is recommended that you always assess the patient's first blood pressure with a sphygmomanometer (blood pressure cuff) and a stethoscope. A pulse oximeter, if available, can be used to assess the level of the patient's oxygenation, but only if there is no impairment of perfusion or exposure to substances such as carbon monoxide that will interfere with accurate readings.

Reassessment

Reassessment is routinely performed during transport. This is a good time to assess more details of the patient's mental status.

Many times, patients with abnormal behavior may have settled down physically, but their minds may still be in a state of flux; this could lead to very impulsive behavior. Monitor patients vigilantly for sudden changes in thought or behavior, particularly as you near the hospital. If patients do not want help, they may try to jump from the ambulance or hurt themselves. Patients will not hesitate to hurt you while attempting to exit the vehicle. Do not put yourself at risk. Medical and traumatic conditions may cause deterioration in a condition identified earlier in the assessment.

You should try to give the receiving hospital advance warning when a patient experiencing a psychiatric emergency is coming in. Many hospitals require extra preparation to ensure that appropriate staff and room are available to accommodate the patient's needs and to ensure safety for all.

Report whether restraints will be required when the patient arrives at the hospital.

Provide thorough and careful documentation in your patient care report. Think about what you are going to write before you write it, so that you can describe what are often confusing scenes as clearly as possible. Because psychiatric emergencies may present with few or no physical signs, your report may be the only documentation of the patient's distress. Psychiatric emergencies are fraught with legal dangers, so it is wise to document everything that occurred on the call, particularly in a situation that required restraints. When restraints are implemented to protect you or the patient from harm, include why and which type of restraints were used. This information is essential if the case is reviewed for medicolegal reasons.

Emergency Medical Care

Treatment of the patient with a psychiatric problem follows the approach stressed throughout this text. First, ensure scene safety; then, when safety is confirmed, focus on life-threatening conditions. If

the erratic behavior might possibly be caused by a medical disorder (eg, hypoglycemia, overdose, or hypoxia), treat the patient for the medical disorder before presuming that the patient's behavior is a result of an emotional or psychiatric cause. These treatment measures may include oxygen therapy, testing of the blood glucose level, and administration of D₅₀ (25 grams of dextrose in 50 mL of water), as well as general interventions for hypothermia or shock management.

Throughout your care of the patient, maintain safety for the patient and for yourself. By placing the patient on the stretcher with the straps in place, you will be more in control of the situation if it turns violent. Control violent situations by restraining the patient, if needed. Call immediately for law enforcement assistance if the patient is potentially violent.

Remain with the patient at all times, unless an unsafe situation exists. Avoid challenging the patient's personal space. Always ask permission before touching the patient, and explain procedures before you perform them. Attempt to eliminate or decrease any condition that may distress the patient, such as loud sirens or fast movements. Refrain from

YOU are the Provider

Part 3

As your partner is placing the blood pressure cuff on his arm, the patient suddenly jumps to his feet and makes shooting noises while pointing an imaginary gun around the room. He shouts, "Did I get them? Did I get them?" You and your partner quickly move back from the patient. The officer on scene calls for additional law enforcement. The patient paces back and forth and appears very anxious and agitated. Once additional law enforcement arrives, the decision is made to restrain the patient with handcuffs for his own protection as well as that of the EMS crew. Because his chief complaint is chest pain, you recommend that the patient be transported by ambulance.

Recording Time: 10 Minutes

Respirations	26 breaths/min, clear bilaterally
Pulse	Strong and regular, 120 beats/min
Skin	Warm, dry, and pink
Blood pressure	176/102 mm Hg
Oxygen saturation (Spo₂)	97% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- What is the minimum number of providers who should be present when attempting to physically restrain a patient?
- In which position should this patient be restrained?
- Should a law enforcement officer accompany you in the back of the ambulance or should the officer follow behind the ambulance in the patrol car?

performing procedures that may not be absolutely necessary, such as starting an intravenous line, if no medical issue exists. Remember to document only objective findings and avoid being judgmental. The patient did not ask for this problem, and you must view it as any other type of illness. If there is any indication of overdose or reason to suspect the patient may have taken something, bring any medications or drugs found to the medical facility.

Words of Wisdom

Altered mental status may be a sign of hypoxia or hypoglycemia. Never withhold oxygen from any patient or discount its use because the patient has a history of mental problems. Check the patient's blood glucose level to rule out hypoglycemia.

Assessment and Management of Specific Emergencies

Acute Psychosis

Psychosis is a state of delusion in which the person is out of touch with reality. Affected people live in their own reality of ideas and feelings. To the person experiencing a psychotic episode, the line between reality and fantasy is blurred. That reality may make patients belligerent and angry toward others. Patients may become silent and withdrawn as they give all their attention to the voices and feelings within.

Psychoses or psychotic episodes occur for many reasons. The use of mind-altering substances is one of the most common causes, and that experience may be limited to the duration over which the substance is metabolized within the body. Other causes may include intense stress, delusional disorders, and, more commonly, schizophrenia. Some psychotic episodes last for brief periods; others last a lifetime.

Disorganization and **disorientation** are *not* diagnoses, but rather ways in which various conditions such as schizophrenia and organic brain syndromes may present themselves. These presentations account for many EMS calls, particularly those involving older people. Although you do not need to make a specific diagnosis in such cases, you do need to know how to manage these patients in the field.

Schizophrenia

Schizophrenia is a complex disorder that is not easily defined or easily treated, yet has a dramatic effect on society. According to the Centers for Disease Control and Prevention, worldwide prevalence of schizophrenia is estimated to be less than 0.5%.⁶ The typical onset occurs during early adulthood, with dysfunctional symptoms becoming more prominent over time. Some people diagnosed with schizophrenia display signs during early childhood; their disease may be associated with brain damage sustained early in life. Other influences thought to contribute to this disorder include genetics, neurobiologic influences, and psychological and social influences.

People with schizophrenia may experience delusions, hallucinations, apathy, mutism, a flat affect, a lack of interest in pleasure, erratic speech, emotional responses, and motor behavior (either a lack of motor behavior or excessive motor behavior). Because the precise causes of schizophrenia are complex and not completely understood, treatments focus on managing symptoms and solving problems related to daily living.⁷

Assessment of Psychosis

The most characteristic feature of psychosis is a profound thought disorder, often accompanied by disturbances in mood and perception. Patients are usually incoherent or rambling in their speech, although they may be oriented to person and place. Often these patients are found wandering aimlessly down the street, dressed oddly, uttering meaningless words and sentences. A thorough examination of the patient is rarely possible, and the principal objective for the AEMT is to transport the patient to the hospital in an atraumatic fashion.

The COASTMAP mnemonic is one way to remember the signs and symptoms commonly associated with patients experiencing a psychotic episode:

- **Consciousness.** The patient is awake and alert, but may be easily distracted, especially if paying attention to hallucinations. If the patient's level of consciousness fluctuates, suspect an organic brain syndrome.
- **Orientation.** Disturbances in orientation are more common in organic disorders than in psychoses, but the patient experiencing severe

psychosis may be disoriented as to time and place.

- **Activity.** Activity is most commonly accelerated, with agitation and hyperactivity, but it may also be diminished. Bizarre, stereotyped movements are common.
- **Speech.** Speech may be pressured or sound strange because of unusual words that the patient has invented (neologisms).
- **Thought.** Thought is disturbed in progression and content and may show any of the following disorders:
 - Flight of ideas, with the patient's mind plunging from one thought to another.
 - **Loosening of associations**, in which the logical connection between one idea and the next becomes obscure, at least to the listener. In extreme cases, the patient's speech may be entirely incomprehensible.
 - Delusions, especially of persecution.
 - **Thought broadcasting** (the patient's belief that their thoughts are broadcast aloud and can be heard by others).
 - **Thought insertion** (the patient's belief that thoughts are being thrust into their mind by another person) and **thought withdrawal** (the patient's belief that thoughts are being removed).

Documentation and Communication

Patient-Centered Communication

The AEMT's personal style of dealing with people—manner of speech, values, beliefs, and ability to listen—is an integral part of the treatment of patients with psychiatric disorders. It is vital to suspend any judgment of the patient and provide the patient with a sense of emotional safety. Patients with psychiatric disorders may not be aware why they are feeling agitated, tense, depressed, or chaotic and out of control. The AEMT must provide a sense of safety in this situation so the patient will trust the provider and thus allow the provider to help. Unfortunately, many patients have life experiences that have eroded their sense of the world as a safe place, which means the burden falls on the AEMT to go the extra mile.

To help establish trust with the patient, use a number of techniques, including maintaining cultural sensitivity. Psychiatric disorders are viewed differently across cultures, and norms of interpersonal space and eye contact vary widely. Be sensitive to these differences.

In addition, the medic should extend respect to earn the patient's trust. It is easy for the patient to judge if the responder is approaching with genuine compassion for the patient as a human being. If an AEMT's first internal reaction is, "This patient is an irresponsible jerk," chances are the patient has just as quickly decided that the AEMT is insincere and cannot be of help. Approach each patient, regardless of their appearance or demeanor, as a fellow human in the grip of something the patient cannot escape without assistance.

When an individual has a psychiatric disorder, you should acknowledge that patient's distress. Identify with the patient's internal struggle. Convey the message that

while you do not feel what the patient is feeling, you can see how they would feel that way (eg, "That must be very frustrating," "Let's talk more about that").

Listen actively, and respond rather than react. Focus on what the patient is saying and respond with your own paraphrasing of the patient's words and emotions. The goal is to make sure the patient feels understood. Keep at it, clarifying where necessary. Above all, do not offer solutions and give advice. You might be tempted to jump ahead with answers or options before the patient is ready to hear them, but resist this urge. Active listening does not mean probing or bombarding the patient with a series of questions that are answered with a simple "yes" or "no." It does not mean offering false reassurance ("This is all going to work out fine"). It does not mean identifying with the patient with inappropriate self-disclosure ("I know about this. I just had a fight with my husband yesterday."). Instead, active listening means understanding the patient, engaging the patient in the treatment process, exploring the problem, acknowledging the patient's feelings (particularly as a way of defusing negative feelings), and even responding to delusions and hallucinations.

To promote active listening, take these steps:⁸

- Sit upright and face the patient.
- Lean slightly forward toward the patient.
- Maintain an open posture (arms and legs uncrossed).
- Make comfortable, non-staring eye contact.
- Relax.
- Be attentive.
- Nod and encourage the patient (eg, "Go on").
- Avoid interruptions.

- **Memory.** Memory can be relatively or entirely intact in psychosis. It may be difficult to obtain the cooperation of the patient for formal memory testing.
- **Affect and mood.** Mood is likely to be disturbed in psychosis. The disturbance may take the form of euphoria, sadness, or wide swings in mood; affect may reflect those inner states or be flat.
- **Perception.** Auditory hallucinations are common in psychosis. Patients hear voices commenting on their behavior or telling them what to do. Suspect that patients are hearing such voices when they seem to be attending a conversation other than yours or talking to themselves.

Management of Psychosis

Dealing with a patient with acute psychosis is difficult. The usual methods of reasoning with a patient are unlikely to be effective because the person experiencing a psychotic episode has their own rules of logic that may be quite different from those that govern nonpsychotic thinking. Furthermore, you are likely to feel uncomfortable in the presence of a person experiencing a psychotic episode. Those uncomfortable feelings are one of your built-in diagnostic instruments. They are elicited by the fear, suspicion, and hostility that the patient is broadcasting through body language. Use your uncomfortable feelings to help make a tentative diagnosis that the patient is experiencing a psychotic problem.

The disorganized patient needs structure. You should explain in plain language what is being done and what the patient's role will be. Directions should be simple, consistent, and firm. It may be impossible to obtain a detailed history directly from the patient; a name and address may be all the information that you can gather. Explain to the patient that they need to be seen by a physician and that you will take the individual to the hospital to get help.

In managing the disoriented patient, the key is to *keep orienting the patient* to time, place, and the people in the environment. Tell the patient who you are, and explain what you are doing. You may have to repeat that information several times en route. Reassure the patient, and point out landmarks to help orient the patient.

Nonpharmacologic techniques, such as maintaining an emotional distance, explaining each step of the assessment, and involving people whom the patient trusts, should be the methods you try first. Consider paramedic backup for administration of a sedative or antianxiety drug if the patient is not compliant and possibly represents a danger to self or to others.

Suicide

The single most significant factor that contributes to suicide is depression.⁹ Any time you encounter a patient experiencing depression, you must consider the possibility of suicide. Risk factors for suicide are listed in **TABLE 24-5**.

It is a common misconception that people who threaten suicide never commit it. This is not correct. Suicide is a cry for help. Threatening suicide is an indication that the person is experiencing a crisis that they cannot handle. Immediate intervention is necessary.

Whether or not the patient has any of these risk factors, you must be alert to the following warning signs:

- Does the patient have an air of tearfulness, sadness, deep despair, or hopelessness that suggests depression?
- Does the patient avoid eye contact (although this may sometimes be a culturally based behavior), speak slowly or haltingly, and project a sense of vacancy, as if the patient really is not there?
- Does the patient seem unable to talk about the future? Ask the patient if they have any upcoming vacation plans. Suicidal people consider the future so uninteresting that they do not think about it; people who are seriously depressed consider the future so distant that they may not be able to think about it at all.
- Is there any suggestion of suicide? Even vague suggestions should not be taken lightly, even if presented as a joke. If you think that suicide is a possibility, do not hesitate to bring the subject up. You will not “give the patient ideas” if you ask directly, “Are you considering suicide?”
- Does the patient have any specific plans relating to death? Has the patient recently prepared

TABLE 24-5 Recognizing the Risk of Suicide**Risk Factors for Suicide**

- Alcohol or other substance abuse
- Hopelessness
- Impulsive and/or aggressive tendencies
- History of trauma or abuse
- Major physical illness
- Previous suicide attempt
- Family history of suicide
- Job or financial loss
- Loss of relationships
- Easy access to lethal means
- Local clusters of suicide
- Lack of social support and sense of isolation
- Stigma associated with asking for help
- Lack of health care, especially mental health and substance abuse treatment
- Cultural and religious beliefs, such as the belief that suicide is a noble resolution of a personal dilemma
- Exposure to others who have died by suicide (in real life or via media and Internet)

Warning Signs for Suicide

- Ideation or defined lethal plan of action that has been verbalized and/or written
- Talking about wanting to die and making statements such as "I wish I were dead"
- Looking for or obtaining a way to kill themselves, such as searching online for or buying a gun
- Being preoccupied with death, dying, or violence
- Talking about feeling hopeless or having no reason to live
- Talking about feeling trapped or in unbearable pain
- Talking about being a burden to others
- Increasing use of alcohol or drugs
- Acting anxious or agitated
- Doing risky or self-destructive things such as driving recklessly
- Exhibiting changes in eating or sleeping patterns
- Giving away belongings or getting affairs in order when there is no apparent explanation for doing so
- Withdrawing from social contact, wanting to be left alone
- Showing rage or talking about seeking revenge
- Exhibiting extreme mood swings
- Saying goodbye to people as if they will not be seen again

a will? Given away significant possessions or advised close friends what to do with them? Arranged for a funeral service? These are critical warning signs.

Consider also the following risk factors for suicide:

- Are there any unsafe objects in the patient's hands or nearby (eg, a sharp knife, glass, poisons, or a gun)?
- Is the environment unsafe (eg, an open window in a high-rise building, a patient standing on a bridge or precipice)?
- Is there evidence of self-destructive behavior (eg, partial cuts on the body; lacerations in various stages of healing on the thighs, upper arms, or other areas that can be easily covered; large alcohol or drug intake)?
- Is there an imminent threat to the patient or others?
- Is there an underlying medical problem?

Remember, the patient considering suicide may be homicidal as well. Do not jeopardize your life or the lives of your fellow AEMTs. If you have reason to believe that you are in danger, you must enlist the aid of law enforcement personnel. In the meantime, try not to frighten the patient or make the patient suspicious.

When a person has *attempted* suicide, medical treatment takes priority. The patient who has taken an overdose of sedative or depressant drugs must be managed for possible respiratory depression or circulatory collapse. The patient who has slashed their wrists must be treated to control bleeding and restore circulating volume. Nonetheless, if the patient is still responsive, try to establish communication and ask the patient to talk about the situation.

Agitated Delirium

A problem you will sometimes encounter in an EMS response is a patient who is experiencing agitated delirium. **Agitated delirium**, also called excited delirium or exhaustive mania, is a state of global cognitive impairment that is acute in onset and associated with fluctuations in mental status and behavior, inattention, disorganized thinking, and an altered level of consciousness. Delirium is a condition of impairment in cognitive function that can

Special Populations

Behavioral disorders are estimated to affect as many as 13% to 20% of all US children and adolescents.¹⁰ When not treated properly, such a problem will most likely persist into adulthood. Given that suicide was the second leading cause of death in US adolescents in 2018,¹¹ more attention has recently been given to mood disorders, anxiety, and other behavioral problems in this population. Children are also more likely to have coexisting problems (eg, attention deficit/hyperactivity disorder, conduct disorder, and oppositional defiant disorder) along with the more traditional mental health disorders.

Mental health problems in children are difficult to diagnose because the lines between normal and abnormal behavior are less clear in this population. Diagnosis and treatment may be difficult when trying to distinguish among organic, genetic, and environmental causes. Cultural and ethnic factors may also blur the line between normal and abnormal coping mechanisms. The mental status assessment of the child is similar to that of an adult, but it takes the child's developmental level into consideration. Abnormal findings in the developmental and mental status examination are often related to adjustment disorders and stress rather than the more serious disorders. Remember that aggressive behavior may be a symptom of an underlying disorder or disability. Your assessment must include an assessment of suicide risk in any child.

present with disorientation, hallucinations, or delusions. Agitation is a behavior that is characterized by restless and irregular physical activity. By comparison, **dementia** is a more chronic process that produces severe deficits in memory, abstract thinking, and judgment. Although patients experiencing delirium are generally not dangerous, if they exhibit agitated behavior, they may strike out irrationally. One of the most important factors to consider in these situations is your personal safety.

The symptoms of agitated delirium may include hyperactive irrational behavior with inattentiveness and possible vivid hallucinations. Common physical symptoms include hypertension, tachycardia, diaphoresis, and dilated pupils. This condition can lead to rhabdomyolysis or death. Because hallucinations are erroneous perceptions of reality, the patient may perceive you as a threat. Agitation is recognized as a biologic attempt to release nervous

tension; it can result in sudden, unpredictable physical actions in the patient.

If you think that you can safely approach the patient, be very calm, supportive, and empathetic. Be an active listener by nodding, indicating understanding, and by limiting your interruptions of the patient's comments. It is extremely important to approach the patient slowly and purposefully and to respect the patient's territory. Limit physical contact with the patient as much as possible. It is also imperative that the patient not be left unattended, unless the situation becomes unsafe for you or your partner.

Carefully use interviewing techniques to assess the patient's cognitive functioning. Try to indirectly determine the patient's orientation, memory, concentration, and judgment by asking simple questions such as "When did you first begin to notice these feelings?" Through interviewing, try to determine what the patient is thinking. Are the patient's thoughts disorganized? For example, does the patient begin to answer your question and then drift off, only to begin discussing a childhood friend? Is the patient experiencing delusions or hallucinations? Does the patient have any unusual worries or fears? For example, does the patient express anxiety if you go too close to a pile of old newspapers?

Pay particular attention to the patient's ability to communicate clearly, and make notes on the patient's apparent mood. Is the patient anxious, depressed, elated (extremely happy or joyful) under inappropriate circumstances, or agitated? Pay attention to the patient's appearance, dress, and personal hygiene. If you determine that the patient requires restraint because of a threat to self or to others, make sure you have adequate, well-trained personnel available to help you before approaching the patient. If the patient appears to be experiencing an overdose, take all medication bottles or illegal substances with you to the medical facility. The patient should be transported to a hospital with psychiatric facilities capable of handling the condition. Whenever possible, refrain from using lights and siren because these sights and sounds may aggravate the patient's condition.

Mood Disorders

Mood disorders, formally known as affective disorders, are among the most prevalent mental disorders. An estimated 21% of the US population will

experience a mood disorder or major depression at some point in their lives.¹² Although feelings such as depression and joy are universal, mood disorders differ from normal bouts of sadness or happiness. In mood disorders, the changes in affect are accompanied by other symptoms, and the net effect is to cause a major disturbance in the person's ability to function. Patients who experience either depression or mania have a unipolar mood disorder; that is, their mood remains at only one pole of the depression–mania continuum. Patients who alternate between mania and depression (both poles of the continuum) have **bipolar mood disorder**. Most patients with a unipolar mood disorder are depressed. Unipolar mania is relatively rare, with only 5% to 7% of all patients with bipolar disorder having this subtype.¹³

Manic Behavior

Mania is one of the most striking psychiatric conditions. Typically, a bystander or family member calls for an ambulance because the patient is unlikely to believe that anything is wrong. To the contrary, the patient with mania is more apt to report being “on top of the world—never felt better in my life.” People experiencing mania typically have abnormally exaggerated happiness, joy, or euphoria with hyperactivity and insomnia.

Patients experiencing mania are typically awake and alert but are easily distracted. They are also often markedly hyperactive and may report being unable to concentrate. Almost all patients experiencing mania report a significantly decreased need for sleep, and they may go for days without sleeping. In conversation, people experiencing mania are talkative, with pressured and rapid speech. Flight of ideas and delusions of grandeur make it difficult for them to focus on one thing. Patients may report that their thoughts are racing; their monologues may skip rapidly from one topic to another (**tangential thinking**). Their ideas are often grandiose, such as unrealistic plans to embark on a large business venture or to run for high public office. Patients may also believe that they have special powers or that they are famous and wealthy. Their memory is usually intact but may be distorted by underlying delusions. Their affect is elated (the hallmark of mania). The patient seems to be on a “high,” and is unusually and infectiously cheerful. The good cheer may be

quite brittle, however, and the person may quickly become irritable, sarcastic, and hostile with little provocation. A person having an acute manic episode may show psychotic symptoms such as hallucinations.

People experiencing acute manic episodes have a high probability of getting themselves into trouble of one sort or another—for example, going on wild spending sprees, making foolish business investments, driving recklessly, committing sexual indiscretions, or picking fights. Often, it is when the person has gotten into some sort of trouble, or when the behavior has become intolerably disruptive, that an ambulance is summoned.

Because patients with mania are unlikely to consider themselves ill, they may not agree that they need treatment. In dealing with the manic individual, be calm, firm, and patient; do not argue or get into a power struggle. Minimize external stimulation. Talk to the patient in a quiet place, away from other people. (Meanwhile, have your partner obtain the history separately from relatives or bystanders.) When it is time to transport the patient, do not use the siren.

If the patient refuses transport, consult medical control. Obtain law enforcement assistance for transport if medical control indicates that hospital evaluation is necessary.

Depression

More than 7% of US adults (17.3 million) experienced at least one major depressive episode in 2017.¹⁴ It affects women more frequently than men and may occur at any age (the mean age of onset is 32 years).¹⁴ The patient with depression is often readily identified by a sad expression, bouts of crying, and listless or apathetic behavior. The person expresses feelings of worthlessness, guilt, and pessimism. These patients may want to be left alone, asserting that no one understands or cares and that their problems are hopeless.

Depression may occur in episodes with a sudden onset and limited duration; this is common in major depressive disorder, in which the patient feels substantial suffering and pain that interfere with social or occupational functioning. In other cases, the onset of depression may be insidious and chronic in nature. Experiencing signs and symptoms of depression for more days than not for a period of at least 2 years suggests a chronic form of

depression known as dysthymic disorder. The signs and symptoms of dysthymic disorder cause social and occupational distress but rarely require hospitalization unless the person becomes suicidal.

The diagnostic features of depression are most easily remembered by the mnemonic GAS PIPES:

- **Guilt.** Guilt and self-reproach are characteristic features of depression. One way to try to get at the patient's guilt feelings is to ask a question such as "Are you down on yourself?" or "Do you ever feel as if you're worthless?"
- **Appetite.** Appetite is abnormal in depression. Usually it is decreased, but a minority of patients with depression may report increased appetite.
- **Sleep.** Sleep disturbance usually takes the form of insomnia. Typical patients with depression will report that they wake up at 0300 or 0400 hours and cannot get back to sleep.
- **Paying attention.** The patient with depression has an impaired ability to concentrate; the impairment is sometimes severe. Ask the patient, "When you're reading a book or a newspaper, can you get all the way through what you're reading, or does your mind start to wander after a couple of minutes?"
- **Interest.** The patient with depression loses interest in things that were once important and can no longer summon enthusiasm for work or hobbies. You might ask the patient, "Are you a [local team name] fan?" If the answer is yes, ask, "How are they doing this season?" The patient with depression will tell you, "Well, I haven't really been following them lately."
- **Psychomotor abnormalities.** In the patient with depression, psychomotor abnormalities can be increased (from agitation) or slowed. Although many patients with depression seem to do everything in slow motion, a significant percentage show agitated behavior such as pacing, wringing their hands, or picking at themselves.
- **Energy.** People with depression have no energy. They are tired all the time and do not feel like doing anything.
- **Suicidal thoughts.** Most worrisome, people with depression tend to have pervasive and recurrent thoughts of suicide.

Neurotic Disorders

Neurotic disorders are a collection of mental disorders without psychotic symptoms and lacking the intense psychopathology of other mood disorders. These disorders cause many problems for patients, their families, and society in general. Treating neurotic disorders comes at a substantial price; however, the cost to society of not treating these disorders (in terms of lost production and lost efficiency) is probably even greater.

This category of conditions includes **anxiety disorders**, which are mental disorders in which the dominant moods are fear and apprehension. Everyone experiences anxiety occasionally, and a certain amount of anxiety helps people adapt constructively to stress. Patients with anxiety disorders, by contrast, experience persistent, incapacitating anxiety in the absence of external threat. An estimated 19% of adults will experience some form of anxiety disorder in any given year, and 31% will develop such a disorder at some point in their lifetime.¹⁵ Several types of anxiety disorders, including generalized anxiety disorder, phobias, and panic disorder, are likely to elicit a call for an ambulance or affect the delivery of prehospital care.

Generalized Anxiety Disorder

Although some anxiety in everyday activity is normal, when a person worries about everything for no particular reason, or if that worrying is unproductive and the person cannot decide what to do about an upcoming situation, the person may be experiencing **generalized anxiety disorder (GAD)**. To make a diagnosis of GAD, symptoms (anxiety and worry) must be present more days than not for a period of at least 6 months and the worry must be difficult to turn off or control. Nearly 6% of all individuals will experience this type of anxiety disorder at some point in their lifetime.¹⁶ Patients experiencing GAD are often treated with both pharmacologic agents and counseling. The acute symptoms of anxiety and worry can become overwhelming in GAD, however, prompting a family member or coworker to call for an ambulance.

When you are dealing with a patient with GAD, identify yourself in a calm, confident manner. Listen attentively to the patient and talk with the person generally about their feelings.

Phobias

Phobic disorders involve an unreasonable fear, apprehension, or dread of a specific situation or thing. The patient with a **simple phobia** focuses all the anxiety onto one class of objects (eg, mice, spiders, dogs) or situations (eg, high places, darkness, flying). At some point in their lifetime, an estimated 12% of adults have social phobias, or fear of everyday social situations such as fear of going to parties, meeting new people, speaking, or eating in public.¹⁷ When confronted with the feared object or situation, the person with a phobia experiences intolerable anxiety and all of the autonomic symptoms that anxiety brings. The patient usually recognizes that the fear is unreasonable but is unable to do anything about it.

In managing a patient with a phobia, explain each step of treatment in detail before you carry it out: “First we’ll give you oxygen to help you breathe. Then we’re going to move you onto the stretcher, so that we can carry you downstairs.”

Panic Disorder

Panic disorder is characterized by sudden, usually unexpected and overwhelming feelings of fear and dread, accompanied by a variety of other symptoms produced by a massive activation of the autonomic nervous system. Women are more likely to be affected by this condition than are men, at a rate of almost three to one,¹⁸ and the disorder tends to run in families. The attacks usually begin between ages 20 and 30 years. Most affected people can identify a stressful event that preceded their first attack, such as an illness or loss of a loved one. Thereafter, the attacks may come “out of the blue,” without any apparent precipitating stress. If allowed to continue, panic attacks may cause severe restrictions in the patient’s lifestyle. The person may become afraid to go to work, to go shopping, or to leave the house at all, out of fear that an attack will occur away from home. The fear of going into public places is called **agoraphobia** (literally, “fear of the marketplace”).

The classic signs and symptoms of panic disorder are summarized in **TABLE 24-6**. A large percentage of these signs and symptoms, such as palpitations and sweating, are a consequence of autonomic nervous system discharge, whereas others (chest discomfort, paresthesias) may reflect

TABLE 24-6 Signs and Symptoms of a Panic Attack

• Shortness of breath or a sensation of being smothered	• Feeling dizzy, unsteady, light-headed, or faint
• Palpitations or tachycardia	• Trembling or shaking
• Sweating	• Feeling of choking
• Nausea or abdominal distress	• Paresthesias
• Chills or hot flashes	• Chest pain or discomfort
• Fear of dying	• Feeling of losing control or going crazy
• Feelings of unreality or of being detached from oneself	

© Jones & Bartlett Learning.

hyperventilation. The symptoms usually peak in intensity within about 10 minutes and last around an hour altogether.

By the time you arrive at the scene, the patient having a panic attack may be surrounded by many anxious and excited people, who will themselves contribute to the problem. Accordingly, you will need to take the following steps to control the situation quickly:

- Separate the patient from panicky bystanders. If you can find a calm friend or member of the patient’s family, however, having this person present may be helpful.
- Provide a calm environment. The environment should be as calm as possible while you transport the patient to the hospital.
- Be tolerant of the patient’s disability. The patient having an anxiety attack may not be able to cooperate or answer questions at first because of intense fear and distress. Your manner must convey that everything is under control.
- Reassure the patient that the situation is safe. The word *safe* can be a magic pill that will often deescalate symptoms to a more manageable level: “We’re going to take you down these stairs on the stretcher. It’s going to be okay; we’ll go slowly and be careful to keep you safe while we move you.”
- Give the patient’s symptoms a name. Once you have checked the vital signs and the electrocardiogram monitor, you should be in a

position to reassure the patient there is no immediate danger of dying: “I know that your feeling of panic is distressing, but it is not life threatening.”

- Help the patient regain control. Encourage the patient to do things to contribute to the care you provide to the extent possible, to help regain a sense of being in control.

Panic attacks may mimic a range of physical disorders in their presentation. Conversely, symptoms of anxiety may be the presenting complaint in medical conditions such as cardiac dysrhythmias, withdrawal states, anaphylaxis, hyperthyroidism, and certain tumors. For that reason, any patient experiencing a panic attack, especially a first panic attack, should be fully evaluated in the hospital. Hyperventilating patients should not be treated with “paper bag therapy,” that is, rebreathing their exhaled air from a paper bag. Patients whose anxiety results from an unsuspected pulmonary embolism or cardiac problem may experience serious complications and even die of hypoxemia if a paper bag is used. Hyperventilation is best managed initially by coaching patients to slow their breathing until they regain control.

Medicolegal Considerations

The medical and legal aspects of emergency medical care become more complicated when the patient is undergoing a behavioral or psychiatric emergency. Nevertheless, legal problems are greatly reduced when an emotionally disturbed patient consents to care. Therefore, gaining that patient's confidence is a critical task for the AEMT.

Mental incapacity can take many forms, including unresponsiveness (as a result of hypoxia, drugs, or hypoglycemia), temporary but severe stress, or depression. Once you have determined that a patient has impaired mental capacity, you must decide whether the patient requires immediate emergency medical care. A patient in a mentally unstable condition may resist your attempts to provide care. Nevertheless, you must not leave the patient alone; doing so may expose you to civil action for abandonment or negligence. In such situations, you should request that law enforcement personnel handle the patient. Another reason for seeking law enforcement support is that a patient who resists treatment often threatens AEMTs and others. Violent or dangerous people who do not require medical care must be taken into custody by the police.

YOU are the Provider

Part 4

Because handcuffing the patient required that he be placed temporarily in police protective custody, the officer rides with you in the back of the ambulance. As you transport the patient nonemergently to the hospital, you attempt to rule out any medical causes of the patient's irrational behavior. You are able to obtain a capillary blood glucose level of 146 mg/dL.

The patient is now calm and appears relaxed. He asks you to take the handcuffs off. He tells you they are uncomfortable and hurting his wrist. You continue monitoring the patient en route to the hospital. You work with the officer to adjust them to decrease the discomfort. On arrival, you give your report to the emergency department nurse and complete your patient care report while your partner readies the ambulance for your next call.

Recording Time: 17 Minutes

Respirations	20 breaths/min, clear bilaterally
Pulse	Strong and regular, 90 beats/min
Skin	Warm, dry, and pink
Blood pressure	124/82 mm Hg
Oxygen saturation (SpO₂)	97%

8. Is it possible that the patient may be suffering from a traumatic brain injury?
9. If the patient is now cooperating, should you ask the officer to remove the patient's handcuffs?

Words of Wisdom

Some communities have crisis intervention teams (CIT) staffed by law enforcement officers with specialized training in recognizing and managing people experiencing a mental health crisis. The primary role of the CIT is to keep patients from revolving through the criminal justice system and the hospital. Such programs have been successful in establishing long-term care and solutions for people with chronic and persistent mental health issues who may not otherwise have the resources or support to get the help they need.

Consent

When a patient is not mentally competent to grant consent for emergency medical care, the law assumes that consent is implied. For example, the consent of an unresponsive patient is implied. The law refers to this concept as the emergency doctrine: consent is implied because of the necessity for immediate emergency treatment, and there is an inherent implication that an alert person would consent to emergency care. In a situation that is not immediately life threatening, emergency medical care or transportation may be delayed until the proper consent is obtained. Contact medical control or follow local protocols when in doubt.

In situations involving psychiatric emergencies, however, the matter is not always clear-cut. Does a life-threatening emergency exist or not? If you are not sure, you should obtain online medical direction and request the assistance of law enforcement personnel.

Limited Legal Authority

As an AEMT, you have limited legal authority to require or force a patient to undergo emergency medical care when no life-threatening emergency exists. Patients have the right to refuse care. However, most states have legal statutes regarding the emergency care of mentally ill and drug-impaired people. These statutory provisions permit law enforcement personnel to place such a person in protective custody so that emergency care can be provided. Medical direction may also order transport of a patient who does not consent to transport. You should be familiar with your local and state laws regarding these situations.

The typical provision may state that:

Any police officer who has reasonable cause to believe that a person is mentally ill and dangerous to himself, herself, or others, or gravely disabled, may take such person into custody and take or cause such person to be taken to a general hospital for emergency examination.

Again, because these provisions vary, you should become familiar with those in your state.

The general rule of law is that a competent adult has the right to refuse treatment, even if life-saving care is involved. In psychiatric cases, however, a court of law would consider your actions in providing life-saving care to be appropriate, particularly if you have a reasonable belief that the patient will commit self-harm or harm others without your intervention. Additionally, a patient who is in any way impaired—whether by mental illness, medical condition, or intoxication—may not be considered competent to refuse treatment or transportation. These situations are among the most perilous you will encounter from a legal standpoint. When in doubt, consult your supervisor, police, and/or medical control. Always maintain a pessimistic attitude toward your patients' condition: assume the worst and hope for the best. Err on the side of treatment and transport. It is far easier to defend yourself against charges of battery than it is to justify abandonment.

Words of Wisdom

When a patient is not mentally competent to grant consent for emergency medical care, the law assumes that there is implied consent to treat immediately life-threatening conditions.

Restraint

Ordinarily, restraint of a person must be ordered by a physician, a court order, or a law enforcement officer. If you restrain a person without authority in a nonemergency situation, you expose yourself to a possible lawsuit, as well as to personal danger. Legal actions that can be taken against you can involve charges of assault, battery, false imprisonment, and violation of civil rights. You may use restraints only to protect yourself or others from bodily harm or to prevent the patient from committing self-harm.

FIGURE 24-2 You may use restraints only to protect yourself or others or to prevent a patient from self-harming.

© Jones & Bartlett Learning.

(**FIGURE 24-2**). In either case, you may use only reasonable force as necessary to control the patient, and different courts may define “reasonable force” differently. For this reason, you should always consult medical control and contact law enforcement for help before restraining a patient.

In fact, you should routinely involve law enforcement personnel if you are called to assist a patient in a severe behavioral or psychiatric crisis. They will provide physical backup in managing the patient, can serve as the necessary witnesses, and will provide legal authority should physical restraint become necessary. A patient who is restrained by law enforcement personnel is in their custody.
